Pre-stressed concrete deck unit bridges were commonly used in the construction of roadway bridges in Queensland, Australia. Many of the existing pre-stressed concrete deck unit bridges were designed and constructed over 60 years ago. With industrial development, these bridges are now required to carry heavier and larger vehicles than those they were designed for and the continual evolution of bridge design codes have introduced more stringent design requirements, which many of these bridges do not now meet. An assessment carried out by the Queensland Department of Transportation and Main Roads (TMR) has identified that some of the pre-stressed deck unit bridges do not satisfy design code requirements and require interventions. Conventional strengthening options available for methods used in RC bridge strengthening are cumbersome, require long time periods to complete, and result in traffic disruptions driving the costs of such interventions quite high. Therefore, strengthening solutions which are less cumbersome and do not involve long periods of traffic disruptions are required to address the current strengthening needs of these pre-stressed concrete deck unit bridges.

Fibre reinforced polymer (FRP) composite materials have gained wide acceptance as an attractive material for strengthening reinforced concrete (RC) structural elements (Büyüköztürk et al. 2004, Hollaway and Teng 2008). The use of FRP, which is a lightweight, easy to install, and highly resistant to corrosion material, provides an attractive alternative to the existing cumbersome traditional strengthening methods. Many types of strengthening methods have been proposed and applied to adapt to the various requirements in practice, such as externally bonded (EB) FRP strengthening, near surface mounted (NSM) FRP strengthening and so called hybrid bonded FRP system (Hollaway and Leeming 1999, Lamanna et al. 2004, Lorenzis and Teng 2007, Yun et al. 2008). Amongst these strengthening methods, EB FRP and NSM FRP strengthening systems have been studied extensively for flexural strengthening of RC beams. Although there is an ever-expanding research database of RC structures strengthened with different FRP systems, information on various strengthening techniques for pre-stressed concrete structures is very limited. Amongst the existing studies, use of EB CFRP plates (Takacs and Kanstad 2000; Reed and Peterman 2004) and the use of NSM CFRP (Hassan and Rizkalla 2002) have

shown to significantly increase the flexural strength of pre-stressed concrete girders. In many of these studies, the use of U-wraps in conjunction with EB CFRP plates or NSM CFRP is advised to avoid premature debonding failures.

This paper presents an experimental study carried out to explore the feasibility of strengthening pre-stressed deck unit bridges in Queensland to increase both flexural capacity and flexural stiffness of the deck units.

EXPERIMENTAL PROGRAM

Test Girders

As a part of an ongoing research program in collaboration with Queensland TMR, two 9.05m long pre-stressed concrete bridge deck units were tested in the Structures Laboratory at the University of Queensland (UQ). One deck unit was tested as the control specimen and the other deck unit was strengthened using an innovative FRP system. Both deck units were of rectangular cross section (Figure 1c-d). The deck units were taken from a decommissioned bridge in Queensland, Australia which was erected between 1963-1970 (exact date unknown). The girders were in good condition upon delivery to the UQ Structures Laboratory. Five core samples per deck unit were tested per AS 1012.14 (1991) to determine the concrete compression strength. The tested compression strength of concrete ranged from 55MPa to 84MPa. Each deck unit is pre-stressed with twenty two 9.7mm diameter pre-stressing strands. According to the fabrication drawings, a pre-stressing force of 70kN was applied to each strand. Three strand samples were cut out from the two tested deck units and tested as per AS1391 (2007). The elastic modulus of steel strands varied from 182GPa to190GPa, 0.2% proof stress varied from 1500MPa to 1650MPa, and ultimate strength varied from 1672MPa to 1840 MPa. In a bridge, ten of these deck units are connected together through transverse steel bars at four locations along the length as shown in Figure 1a. Each deck unit consists of two rows of internal voids of 150mm diameter along the longitudinal axis of the beam (Figure 1a-c). The camber of the deck units at mid-span, due to pre-stressing and self-weight was measured to be 21mm and 19mm respectively.

Figure 1. Details of the pre-stressed bridge deck units

Strengthening Scheme

The preliminary investigations carried out by TMR revealed that such deck units may fail due to inadequate flexural capacity or due to shear failure through transverse connections. The aim of the transverse connections through ten deck units in a bridge is to provide effective load distribution amongst the deck units, thus allowing the ten deck units to act as a single system rather than as individual deck units. However, once the load-displacement behaviour of a deck unit becomes nonlinear, due to the reduction of flexural stiffness, the forces transferred through the transverse bars may significantly increase. Thus increasing the risk of failure in the deck unit near the transverse bar locations or failure in the transverse bar itself. Therefore, a strengthening system which could increase both the flexural capacity and flexural stiffness (especially when the behaviour becomes nonlinear) is required for the effective strengthening of these pre-stressed deck unit bridges.

(c) Mechanical anchor and adhesive bond

Figure 2. Strengthening details of the test specimens

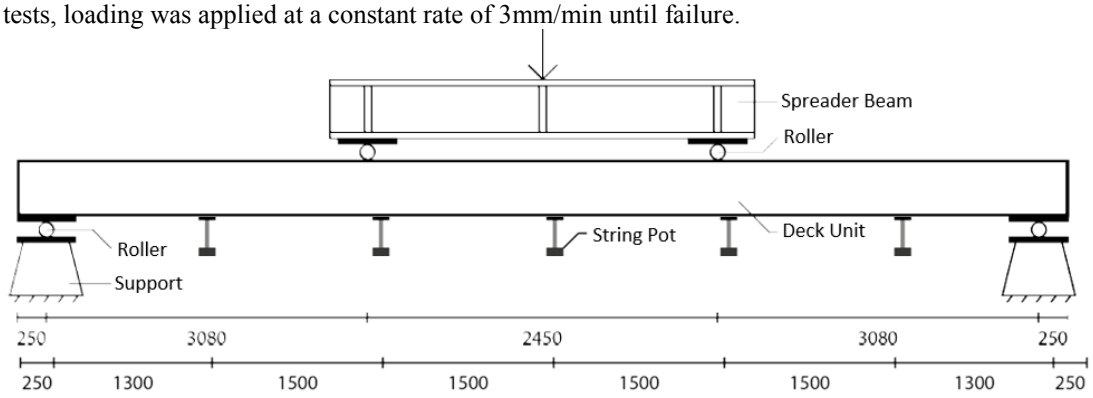
A novel strengthening scheme (Figure 2) which consists of three 8m long glass FRP (GFRP) I profiles and three 8m long carbon FRP (CFRP) pultruded plates was designed in this study to increase flexural capacity as well as

the flexural stiffness of the pre-stressed concrete deck units. Commercially available GFRP I beams, with a longitudinal elastic modulus of 29GPa and tensile strength of 434MPa, were used in this study. The cross sectional dimensions of the GFRP I beams used in this study are given in Figure 2b. GFRP I beams were bonded to the soffit of the pre-stressed concrete deck units using MBrace laminate adhesive. Due to the relatively high flexural stiffness of the GFRP I beam (compared to that of commonly used CFRP pultruded plates), high interfacial peeling stresses may result near the GFRP I beam termination points. In addition, during the testing cracks may appear on the soffit of the concrete deck unit resulting in high peeling stresses within the bonded interface near those cracks. A preliminary FE model was used to estimate the peeling forces expected near the GFRP I beam termination points. Based on this estimate, M8 DynaBolts were used on either side of the flange at 300mm cc distance to provide resistance against peeling stresses. Embedded length of DynaBolts within concrete was controlled at 32mm. A 102mm wide, 1.4mm thick CFRP pultruded plate (170GPa) was bonded to the underside of the bottom flange of each GFRP I beam using MBrace laminate adhesive.

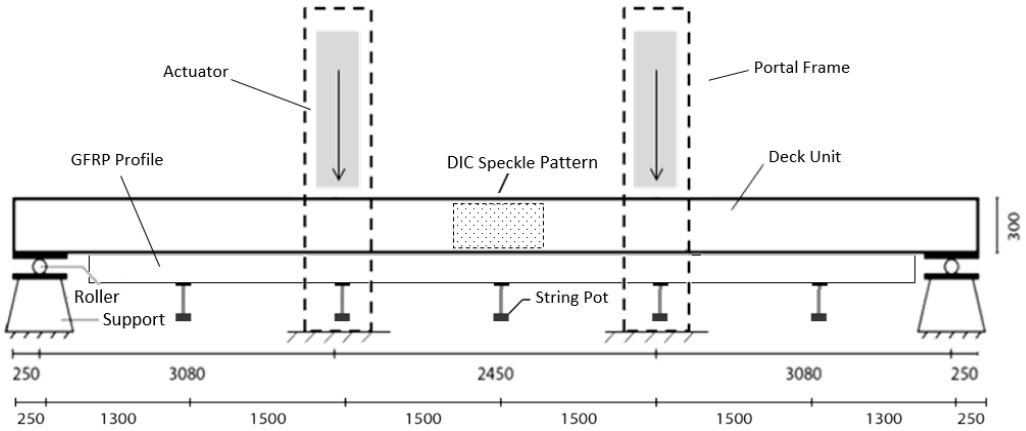
All the materials were purchased at commercial rates. Price of the GFRP I beams were AUD $ 62.5/m while price per CFRP pultruded plate was AUD $50/m. Total material cost of strengthening per pre-stressed deck unit was AUD $ 2,524.60. This translates to AUD $ 25,246 in material costs for strengthening a pre-stressed deck unit bridge (with 10 deck units). Specimens were prepared at the UQ structures laboratory by three undergraduate students with no previous FRP strengthening experience. Minimal labour and equipment costs are expected for such a strengthening exercise.

Test Setup and Instrumentation

Both the control specimen and the FRP strengthened specimen were tested under 4-point bending, while two different test frames were used in two tests. The control specimen was tested using a 1MN capacity MTS hydraulic testing machine, with a spreader beam spanning 2.45m between two loading points (Figure3a). The FRP strengthened specimen was tested using two 250kN capacity MTS hydraulic actuators (which were not available for the control specimen) under a 4-point bending test setup as schematically shown in Figure 3b. In both tests, loading was applied at a constant rate of 3mm/min until failure.



(a) Test setup for the control beam



(b) Test setup for the strengthened beam

Figure 3. Schematic diagrams of the test setups

In both tests, five displacement transducers were used at the bottom of the deck unit to measure beam deflection at different locations (Figure 3a,b). On the control specimen, strain gauges were attached to the compression face as well as the tension face of the deck unit to measure axial strains (i.e. strains parallel to the longitudinal axis) as shown in Figure 4a. In addition, strain gauges were also attached on the side face of the deck unit at mid-span to measure axial strain distribution along the height of the specimen (Figure 4b). On the FRP strengthened specimen, strain gauges were attached to the underside of the CFRP plates (Figures 5a-d), as well as on the underside of the top flange of one of the GFRP I beams as shown in Figures 5a and e. In addition strains on the side of the deck unit at mid-span were measured using a digital image correlation (DIC) system (which was not available for the control specimen).

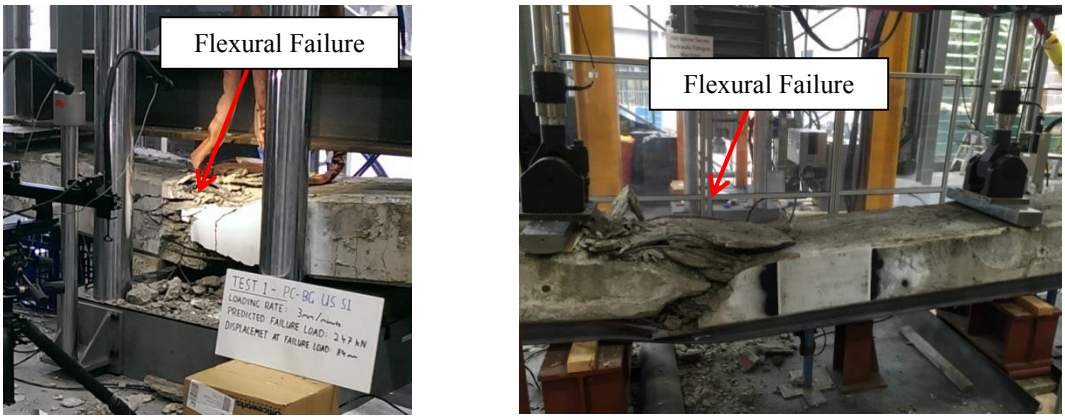
RESULTS AND DISCUSSION

All the tested deck units were uncracked prior to testing. Cracking of the control specimen started at approximately 107kN, with the load displacement curve also starting to become nonlinear around the same load. As the load increased, flexural cracks were evenly distributed along the length between the loading points. The control specimen ultimately failed due to concrete crushing at a load of 200.3kN with an ultimate displacement of 250.9mm. Chips of concrete started to fall off the top surface of the concrete deck unit approximately at mid-span just before the ultimate load was reached, soon followed by an explosive brittle failure (Figure 6a). The load-deflection behaviour as well as the load-mid-span compressive strain behaviour is shown in Figures 7 and 8 respectively. Both these plots do not include the camber of the deck unit. The maximum concrete compressive strain at failure was measured as 0.00275.



(a) Control specimen (b) Strengthened specimen

Figure 6. Failed specimens

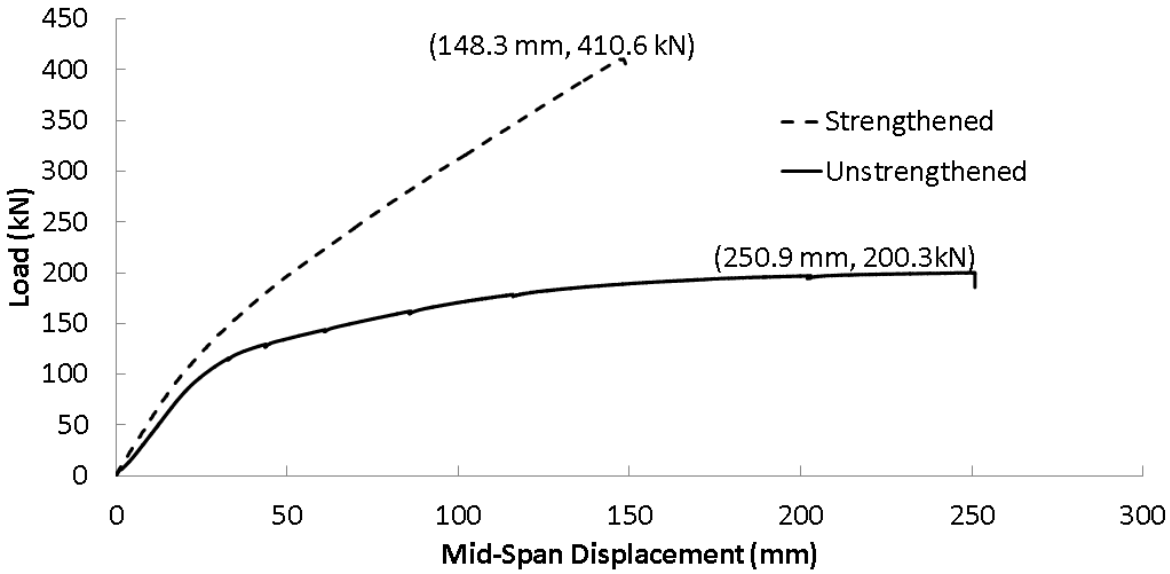


Figure 7. Load vs mid-span deflection curves

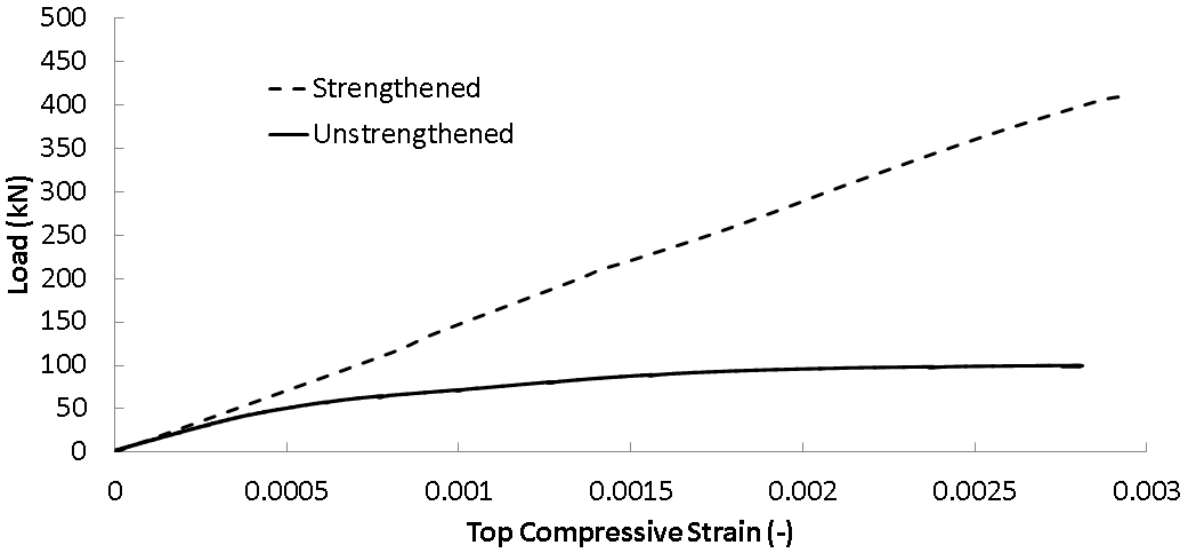

Figure 8. Load vs mid-span compressive strain

The FRP strengthened specimen showed an increase in the initial flexural stiffness, with a significant increase in the stiffness as the load-deflection behaviour became nonlinear (Figure 7). Cracks on the soffit of the deck unit did not appear until approximately 100kN. The size of the crack openings were shown to be much less than that of the cracks in the control specimen. The number of flexural cracks observed was much less than that observed in the control specimen. The load-deflection curve starts to become nonlinear at approximately 100kN. No visible debonding of the GFRP I beams from concrete substrate or CFRP plate from GFRP I beam was observed during the testing. At approximately 400kN, cracks which were parallel to the top surface started to appear next to the left side actuator. The FRP strengthened specimen ultimately failed due to concrete crushing (Figure 6b) at a load 410.6kN with an ultimate displacement of 148.3mm. The concrete compressive strain at failure was measured as 0.00292. The FRP strengthening increased the flexural capacity by 105%.

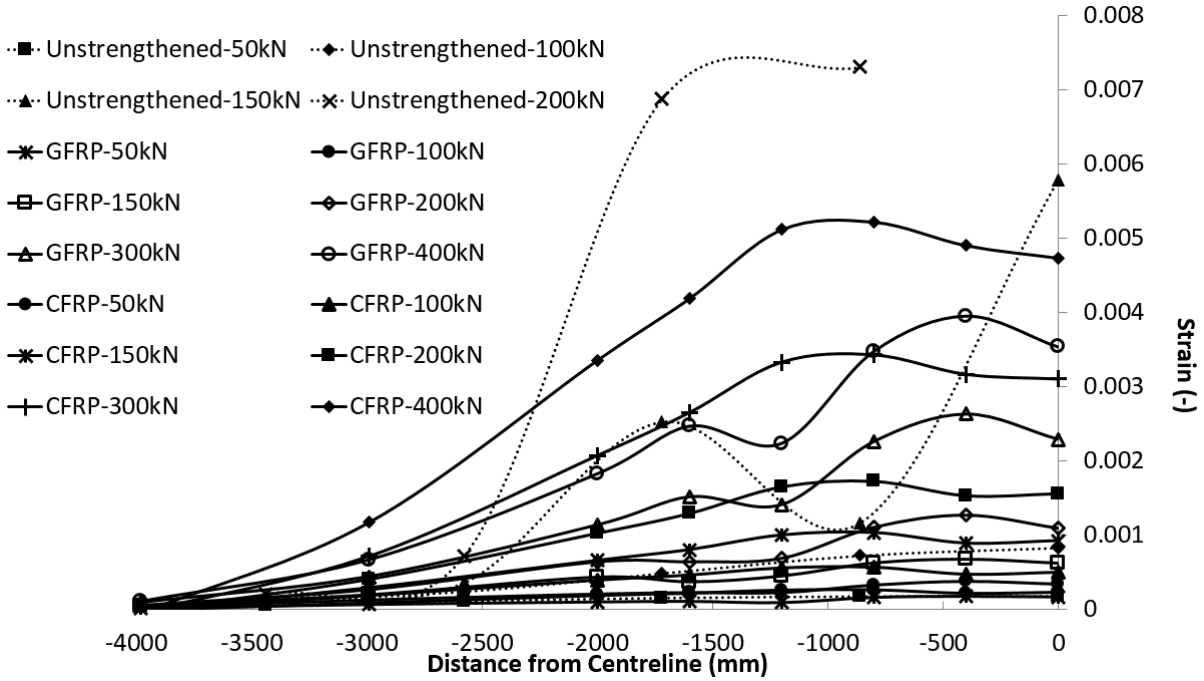

Figure 9. Axial strain distributions

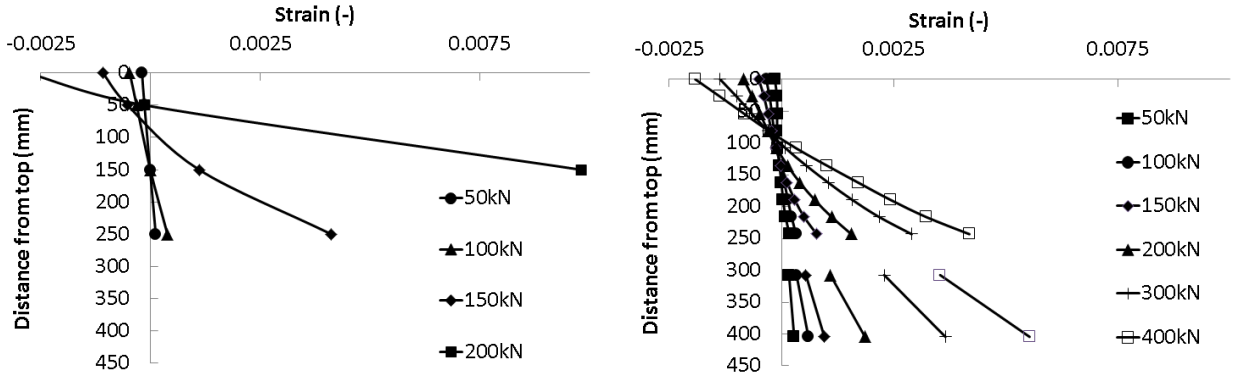
Axial strain distribution along the length of the deck units at different loads, from the strain gauges C1-6 to C1-10 (i.e. strain gauges attached to the bottom face, Figure 4a) for the control specimen, and from the strain gauges C2-12 to C2-19 (i.e. strain gauges attached to the underside of the top flange of the GFRP I beam, Figure 5e) and C2-1 to C2-8 (i.e. strain gauges attached to the CFRP plate, Figure 5d) are compared in Figure 9. At 100kN, strain measurements from C1-6 to C1-10 showed higher values than the measurements from C2-12 to C2-19. Given the higher flexural stiffness of the strengthened specimen, these lower strain readings observed on the underside of the GFRP I beam are reasonable. The axial strain readings away from the mid-span, from the CFRP plate (i.e. C2-1to C2-5) at 100kN were also found to be similar to the strain readings from the tensile face of the control specimen (i.e. readings from C1-6 to C1-8) at the same load. However, strain measurements from C1-9 and C1-10 in the control specimen were found to be higher near the mid-span, than the strain measurements from C2-6 to C2-8. When the load increased up to 150kN, strain readings from C1-6 to C1-10 were shown to be much higher than the strain readings from C2-12 to C2-19 and C2-1 to C2-8. This pronounced difference is explained by the change in flexural stiffness seen in the two load-deflection curves. The reduction in the strain readings at 860mm away from the mid-span of the control specimen, i.e. C1-9 is believed to be caused by the excessive cracking of concrete. Absence of such clear variations in strain readings from C2-12 to C2-19 and C2-1 to C2-8 indicates less cracking in the strengthened specimen compared to the control specimen. At 200kN loading, strain gauges C1-10 were damaged due to cracking. Strain readings from C1-6 to C1-9 were much larger than the strain readings from C2-12 to C2-19 and C2-1 to C2-8 at the same load. As the load increased, strain readings from C2-5 and C2-16 also showed some reduction in strain compared to the readings from the adjacent strain gauges, which is believed to be due to the cracking of concrete. At the ultimate load, i.e. 410.6kN, maximum strain seen by the CFRP plate was 0.0058, which is only about 32% of its ultimate strain.



(a) Unstrengthened specimen axial strain profile (b) Strengthened specimen axial strain profile

Figure 10. Axial strain variation along the height at mid-span

The axial strain variation along the height of the specimen at mid-span measured, from the strain gauges C1-5, S-1 to S-3 for the control specimen, and DIC system and C2-19 and C2-8 for the strengthened specimen are given in Figures 10a and 10b respectively. At lower loads, axial strains at the mid-span of the control specimen showed a linear distribution along the height. As the load increased, this became nonlinear which is believed due to the cracking of concrete in the tension face. The neutral axis moved towards the compression side of the beam with the increasing load. The strain distributions within the concrete deck unit of the strengthened specimen also showed linear strain variations, but a discontinuity of the strains from the concrete to GFRP I beam was observed (Figure 10b). This discontinuity became more pronounced as the load increased. This observation indicates some slip at the concrete-GFRP interface.

CONCLUSIONS

This paper has presented the results from an investigation of strengthening of pre-stressed RC bridge deck units employing a novel FRP strengthening scheme. Strengthening of the deck units were carried out by adhesively bonding and mechanically fastening three 8m long GFRP I profiles to the soffit of the pre-stressed RC deck unit, and adhesively bonding a 8m long CFRP plate to the tension flange of each GFRP I beam. Two deck units, one unstrengthened as a control specimen and another strengthened with the novel FRP scheme were tested to failure under 4-point bending. Both beams showed flexural failure with failure occurring in the constant moment region. The control specimen showed significant nonlinear deformation before the ultimate failure, while the strengthened specimen also showed significant deformations before failure. No debonding of the GFRP I beams or the CFRP plates were observed during the testing, demonstrating the effectiveness of the bonding and mechanical anchoring system used in the strengthening scheme. The strengthened beam significantly increased the stiffness of the beam, especially when compared to the nonlinear part of the control specimen load-deflection curve. The strengthening scheme was also shown to be highly effective in increasing the flexural capacity of the pre-stressed deck units, with the tested strengthened deck unit resulting in 105% flexural capacity increase. Cracking of concrete on the tension face was observed in both deck units, with the strengthened deck unit showing much less cracking than the unstrengthened deck unit. Axial strain distribution at the mid-span along the height of the strengthened deck unit showed slip at the GFRP I beam-concrete interface, thus indicating loss of perfect composite action, which may have resulted due to significant cracking of concrete.

ACKNOWLEDGEMENTS

Authors wish to thank Queensland Department of Transportation and Main Roads for providing the bridge deck units for testing, Mr Doherty and Mr Gibbs for their contributions in testing, Mr. Lumsden for his contributions in preparing the specimens, and lab technicians at the UQ structures laboratory for their help in preparation and testing of the specimens.

ABSTRACT

Hybrid simulation is a cost-effective cyber-physical testing technique, in which computational models and physical components are integrated at run-time. This method can be viewed as conventional finite element analysis, where physical models of some portions of the structure are embedded in the numerical model. In such a way, the errors related to the simplification of the theoretical modeling of complex nonlinear structures or subassemblies can be effectively mitigated as they are tested physically in the lab. This paper introduces Australia's first hybrid testing facility, referred to as the Multi-Axis Substructure Testing (MAST) system, which is capable of simulating the complex three-dimensional time-varying boundary effects on large-scale structural components. The MAST system is unique in Australasia and is capable to serve the research community and practice, nationally and internationally. An application of the MAST system to investigate the performance of a CFRP-repaired limited-ductile RC column under sequential ground motions from linear-elastic response range through collapse is also presented.

INTRODUCTION

The reliable prediction of nonlinear behavior of structures such as buildings and bridges and their failure mechanics under extreme loads, especially earthquake loading, poses significant challenges in structural engineering. Researchers implement various methods for studying the behavior of structures under such loading condition. The most common method is to use computational methods and computer simulations. Nowadays, dynamic analysis of complex structures can be efficiently computed utilizing different available software. The cost of computation has been continuously reduced and now very complicated and detailed numerical simulations are possible on personal computers. However, for many components or materials, failure modes are still not well-understood. In such cases, numerical analyses and simulations may not be reliable since more detailed and complex properties are needed for the critical components to obtain meaningful results. In these cases, experimental testing of structures predict their nonlinear behavior in a more accurate and realistic manner. However, testing the entire structure may not be necessary and could be expensive and time consuming. Hybrid simulation is a cyber-physical procedure that combines classical experimental techniques, with online computer simulation and provides a cost-effective platform for large-scale testing of structures under simulated extreme loads.

Hybrid simulation can be viewed as conventional finite element analysis, where physical models of some portions of the structure are embedded in the numerical model. In such a way, the errors related to the simplification of the theoretical modeling of complex nonlinear structures or subassemblies can be effectively mitigated as they are tested physically in the lab. This method is based on splitting the structure considered into two or more substructures and conducting separate analyses on each part, while making sure the interface constraints are continuously verified both in terms of deformation-compatibility and force-equilibrium conditions. The part of the structure that can be reliably modeled numerically, either because they have a simple behavior or because they are not considered being critical for the analysis conducted, is numerical substructures. The part of most interest that are physically tested, either because they are critical to the safety and performance of the structure or a high degree of nonlinearity is expected, is called the experimental substructure. The combination and interactions of the two substructures form a hybrid model of the complete structure of interest. To illustrate this process for the various types of substructures in hybrid simulation, an example is presented for a multi-story concrete structure. Utilizing the hybrid simulation technique, the first-story corner-column that is typically the critical element can be constructed and physically tested in the lab and the remaining parts of the structure, inertia and damping forces and gravity, dynamic loads and the second order effects can be reliably modeled in the computer (Fig.1).

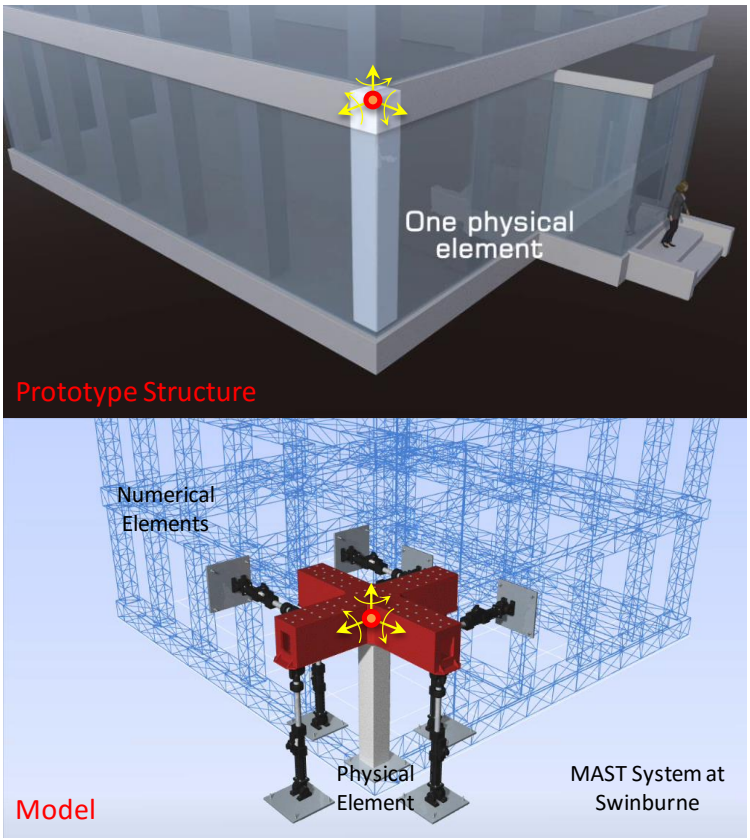

Figure 1. Hybrid simulation technique

Hybrid simulation was originated as the computer-actuator online system by Takanashi et al. (1975) or the pseudo-dynamic testing method (Mahin and Shing, 1985; Nakashima et al., 1992). During the late 1970s, 1980s, and early 1990s, efforts in Japan and the United States were undertaken to expand the capabilities and validation of the hybrid simulation. A comprehensive review of the hybrid response simulation method is presented by Saouma and Sivaselvan (2008). According to a report developed by the U.S. earthquake engineering community, hybrid simulation capabilities are a major emphasis of the next generation of earthquake engineering research (Dyke, 2010).

This paper introduces Australia's first hybrid testing facility, referred to as the Multi-Axis Substructure Testing (MAST) system, which is capable of simulating the complex three-dimensional time-varying boundary effects on large-scale structural components. The MAST system is unique in Australasia and is capable to serve the research community and practice, nationally and internationally. An application of the MAST system to investigate the performance of a Carbon-Fiber Reinforcement Polymer (CFRP)-repaired limited-ductile reinforced-concrete (RC) column under sequential ground motions from linear-elastic response range through collapse is also presented.

AUSTRALIA'S FIRST HYBRID TESTING FACILITY

The hybrid testing facility is located in the Smart Structures Laboratory at Swinburne University of Technology, Melbourne, Australia. The $15million laboratory is a major three-dimensional testing facility developed for large-scale testing of civil, mechanical, aerospace and mining engineering components and systems and the only one of its type available in Australia. The laboratory includes a 1.0m thick strong floor measuring 20m×8m in-plan with two 5m tall reaction walls meeting at one corner and a suite of hydraulic actuators and universal testing machines varying in capacity from 10tonnes to 500tonnes. The laboratory is serviced by adjacent workshops and a hydraulic pump system located in the basement. The facility is housed in the architecturally striking Advanced Technologies Centre and features transparent walls, allowing passers-by to watch researchers and scientists at work.

The hybrid simulation system at Swinburne consists of several components including software and hardware that allow for hybrid testing in various configurations. Currently, the experimental hybrid procedures include

scaled-time hybrid simulation (pseudo-dynamic) with substructuring but can be extended to real-time hybrid simulation and effective force testing. An advanced hardware configuration has been set up to ensure a strong coupling and a very high-speed data communication between the servo-controllers and the main computer solving the equation of motion. Hybrid simulation frameworks include:

1. Multi-Axis Substructure Testing (MAST) system for three-dimensional large-scale structural systems and components.
2. 1MN universal testing machine that is suitable for developers and proof-of-concept tests.
3. Generic actuator configuration system for substructure hybrid simulation tests at system level.

The key components and specification of the MAST system is presented next.

Multi-Axis Substructure Testing (MAST) System

Multi-directional loading on structural components has been performed before in the George E. Brown Jr. Network for Earthquake Engineering Simulation (NEES) facilities in U.S., including the Multi-Axial Sub-assemblage Testing Laboratory located at University of Minnesota, Minneapolis [6] that has been used in quasi-static tests and the Multi-Axial Full-Scale Sub-Structure Testing and Simulation facility at the University of Illinois at Urbana-Champaign [7-8] that has been used in displacement control hybrid simulation experiments. These systems have the capacity for large-scale testing and the ability to control multiple DOFs at the boundary of physical specimen. Building on the same concept, the Multi-Axis Substructure Testing (MAST) system at Swinburne University of Technology has been established to provide a state-of-the-art facility for mixed-mode large-scale quasi-static cyclic testing and local/geographically-distributed hybrid simulation experiments (Fig.2). The key components of the 6-DOF testing facility are:

1. Four ±1MN vertical hydraulic actuators and two pairs of ±500kN horizontal actuators in orthogonal directions. Auxiliary actuators are also available for additional loading configurations on the specimen (Fig.3 and Table 1).
2. A 9.5tonne steel crosshead that transfers the 6-DOF forces from the actuators to the specimen. The test area under the crosshead is approximately three meters cubed.
3. An advanced servo-hydraulic control system capable of imposing simultaneous 6-DOF states of deformation and load in switched and mixed mode control.
4. A reaction system composed of an L-shaped strong-wall (5m tall × 1m thick) and 1m thick strong-floor.
5. An advanced three-loop hybrid simulation architecture including: servo-control loop that contains the MTS FlexTest controller (inner-most loop), the Predictor-Corrector loop running on the xPC-Target real-time digital signal processor (middle-loop) and the Integrator loop running on the xPC-Host (the outer loop).
6. Additional high-precision draw-wire absolute encoders with the resolution of 25microns that can be directly fed back to the controller.

MAST Reaction System

The design of the crosshead in the form of a cruciform was undertaken independently by Swinburne University in collaboration with Hofmann Engineering Pty. Ltd. (Hofmann, 2013). Nonlinear finite element simulations were performed to optimize the design of the MAST steel cruciform. The model included all relevant details such as: holes for base plate connections and stiffener plates. Zones of weakness at weld connections were considered by modeling local elements of lower strength/stiffness in the vicinity of welds. Four load cases were considered to induce the highest possible flexure, shear and torsion within the structure (Fig.4a)

The design of the strong wall/floor was undertaken independently by Waterman International Consulting (Waterman, 2010) engineers in collaboration with Swinburne University. The 3D strong-cell contains a grid of tie down points 0.5m apart to secure the test specimens in place. The 6-DOF hybrid testing facility introduces an array of possible loading conditions to both the strong floor and reaction wall. 3D solid models were constructed to assess the maximum load that may be applied to the reaction wall in any given configuration without exceeding the tensile strength of the concrete. Over 100 load configurations were constructed to determine maximum allowable wall loading in any given scenario (Fig.4b).

MAST Control System

The movement of the MAST crosshead is governed by the collective movement of four vertical and four horizontal actuators. To create a desired crosshead movement, actuators are time synchronized using a DOF control concept (Thoen, 2013). This concept allows the user to control system motion in a coordinate domain

most natural to the test. With multiple actuators positioning the crosshead, it is impractical to control the system by individually controlling each actuator. Therefore, the MTS controller (MTS, 2014) has been programmed to simultaneously control the 6-DOF movement of the crosshead at its datum point, where it is attached to the specimen. In DOF control, the feedbacks for each loop are determined by summing together all individual feedbacks that contribute to that specific DOF, and each actuator drive-signal is determined by summing together all individual DOF error signals that are affected by that actuator. In addition, the MAST system features mixed-mode control, allowing users to specify the displacement or force required for the desired direction of loading to test large-scale structural components.

Also, since the MAST system has eight actuators operating to control 6 DOFs, it is over-constraint. Therefore, in order to manage this redundancy in the actuation system, the controller uses force balance compensation. Since the crosshead is designed to have a very high stiffness, tiny offsets in actuator position can generate large distortion forces. The force imbalances can seriously limit the performance of the system when applying large forces to the specimen. Force wasted in distorting the crosshead, with actuators working against each other, is the force not available to apply to the test specimen. Force balance compensation corrects for this by ensuring that the force is distributed equally among all driving actuators. Further, in order to improve the displacement control resolution in the hybrid simulation of stiff and strong physical specimens, in addition to the actuator's LVDT, the system uses additional high-precision draw-wire absolute encoders (SICK, 2014) with 25micrometers precision for displacement feedback.

b) FE-model of the strong wall/floor

Figure 4. FE analysis for MAST reaction systems

Hybrid Simulation Architecture

The hybrid simulation control system at Swinburne uses xPC-Target and consists of a three-loop architecture (Stojadinovic et al., 2006), which is depicted in Figure 5. The innermost servo-control loop contains the MTS FlexTest controller that sends displacement/force commands to the actuators while reading back measured displacements/forces. The displacements are measured from both the actuator LVDTs and the additional high-precision draw-wire absolute encoders. The middle loop runs the Predictor-Corrector actuator command generator on the xPC-Target (Mathworks., 2009) real-time digital signal processor (DSP) and delivers the displacement/force commands to the FlexTest controller in real-time through the shared memory SCRAMNet (Systran, 2004). Finally, the outer integrator loop runs on the xPC-Host and includes OpenSees (McKenna, 2011), MATLAB (Mathworks., 2009) and OpenFresco (Schellenberg et al., 2009) that can communicate with the xPC-Target through TCP/IP network.

APPLICATION OF HYBRID SIMULATION IN PERFORMANCE-BASED ASSESSMENT OF A CFRP-REPAIRED LIMITED-DUCTILE REINFORCED-CONCRETE COLUMN

The MAST system was used in application for seismic performance-based assessment of a CFRP-repaired limited-ductile RC column. The test specimen was previously damaged in hybrid simulation of a half-scale symmetrical five-story (h_1=2.5m, h_{typ}=2.0m) five-bay (b=4.2m) RC ordinary moment frame building, which was designed for Melbourne. The RC column is 2.5m high with a square 250mm×250mm cross-section and 30mm cover thickness. The compressive strength of the concrete is 35MPa and the specimen is reinforced with 4 longitudinal bars of N16 (reinforcement ratio = 1.28%) and tied with R6 stirrups spaced at 175mm.

Figure 6 shows hybrid simulation components including numerical and experimental substructures. The experimental substructure consisted of the first-story corner-column while the rest of the structural elements, inertia and damping forces, gravity and dynamic loads and second-order effects were modelled numerically in the computer. The frame's beams and columns were modelled using beam-with-hinges element (Scott and Fenves, 2006), where the nonlinear behaviour is demonstrated by using a distributed-plasticity concept that occurs in a finite-length near both ends. The plasticity model followed peak-ordinated hysteresis response based on the Modified Ibarra-Medina-Krawinkler (IMK) deterioration model for the flexural behaviour (Ibarra et al., 2005). The IMK model parameters were calibrated using the results of quasi-static tests and empirical equations provided by Haselton et al. (2008).

In the initial hybrid simulations the structure was subjected to biaxial ground motions, which were the two components of Imperial Valley 1979 El Centro station with peak ground acceleration of 0.15g. Figure 7 shows the acceleration, displacement and acceleration-displacement response spectra of the ground motion components. Four levels of ground motions were used for initial hybrid simulations to cover the structure's response from linear-elastic range through collapse. The scale factors for the level of intensities were 0.6, 4.0, 8.0, 9.0 that pushed the structure to nearly 0.25%, 2.0%, 4% and 6% maximum inter-story drift ratio, respectively.

Figure 7. Response spectra for biaxial ground motions of Imperial Valley 1979

The damaged column contained localized zones of spalled and fractured concrete, horizontal and inclined cracking and bent longitudinal reinforcement at each end of the column. The repair methodology involved: (1) removal of all spalled and fractured concrete; (2) crack injection of any cracks greater than 0.3mm (3) reinstatement of damaged concrete with a suitable repair mortar and (4) wrapping of the column with FRP. Visual inspection and light tapping using a rubber hammer was used to identify and remove fractured concrete. Cracks that required injection were identified and labeled. Epoxy injection ports were drilled into the concrete directly over the crack and bonded to the surface with epoxy resin. The surface of the crack was sealed and the injection carried out using Sikadur® 52 high-strength adhesive. After hardening of the sikadur 52, the injection ports were cut and a repair mortar was used to replace the damaged concrete. BASF MasterEmaco® S 5300, which is a polymer modified structural repair mortar was used for this purpose. The average compressive strength of the repair mortar at the test date was based on the results of three 50×50mm cubes was 41.9 MPa. The mortar was tested in accordance with ASTM C109 (American Society for Testing and Materials, 2011).

The CFRP wapping was applied over a 600mm length at each end of the column in regions corresponding to the maximum moment, three days after the crack injection was performed. The concrete in these regions was confined using three layers of MBrace CF130 unidirectional carbon fiber sheet. The CFRP was expected to provide a passive confinement pressure, thereby increasing the compressive strength of concrete with applied load. Furthermore, the orientation of the fibers was parallel to the existing steel stirrups and was expected to significantly increase the shear capacity at the column ends. The total increase in axial and shear capacity of the

column as a result of the FRP was estimated as 35% and 250% respectively when calculated in accordance with ACI440.2R-08 (American Concrete Institute, 2008).

A summary of the material properties of the FRP and adhesives used in the repair are summarized in Tables 2 and 3. Prior to application of the FRP to the concrete surface, the corners of the column were rounded to achieve a minimum radius of 25mm. A mechanical abrasion technique was used to remove the weak layer of cement laitance adhering to the surface of the concrete and achieve a surface roughness similar to 60 grit sandpaper. The surface was cleaned to remove any dust prior to application of the FRP. The FRP was applied using a wet-lay-up technique where each layer was thoroughly impregnated with resin prior to application to the column. The repairing process was performed while the column was still under the MAST system and subjected and supporting an axial load corresponding to 130 kN. The CFRP was cured at 50 °C for 7 days using heat lamps prior to testing (refer Fig. 8).

Table 2. Summary of FRP material properties

Properties	MBrace CF230	Units

b) Repair of the initial column (Base)

c) Repaired column

Figure 8. CFRP repair of the column previously damaged in sequential hybrid simulations

The hybrid simulation test started with applying 221.26kN gravity load on the specimen followed by bidirectional sequential ground motions. The intensity levels included the same previous four levels of 0.6, 4.0, 8.0, 9.0 and an additional level of 10.0 that pushed the structure to 0.25%, 2.0%, 4%, 6% and 8% maximum inter-story drift ratio, respectively. All the sequence of loading was performed and automated through OpenSees (2015), OpenFresco (2015) and MATLAB (The MathWorks Inc., 2014). Considering 117msec delay in the hydraulic system, 500msec was specified as the simulation time step to provide sufficient time for integration computation, communication process, actuator motions and data acquisition. This scaled the 60 second of sequential ground motions in real time to a 6 hours test in laboratory time. Note that, slow loading of the

structure is important so as not to excite its inertial and damping properties, which are already accounted for computationally.

Figure 9 summarizes the hybrid simulation test results including the comparison of hysteresis in X and Y axes and axial force time history in Z-axis. Compared to the initial column, it can be observed that the repaired column has lower strength in low level deformations as a result of buckling of longitudenal rebars exsited from the initial damage. In large deformations, however, the repaired column shows similar strength and improvement of stiffness, which is due to the increase of ductility by confinement of concrete using CFRP wraps.

CONCLUSIONS

Hybrid simulation is a cost-effective method for experimental testing of large-scale structures. This paper introduced Australia's first hybrid testing facility, referred to as the Multi-Axis Substructure Testing (MAST) system, for cost-effective large-scale testing of structural components. The system was used in application for seismic performance assessment of a CFRP-repaired limited-ductile RC column that was previously damaged in similar hybrid simulation test series. The repaired column showed comparable strength and improved stiffness compared to the initially damaged column in large deformations.

ABSTRACT

Reinforced concrete slab bridges are of excellent integrity, small beam hight and flexible structure. In order to adapt to the topographic condition，road alignment and traffic function in practical engineering, the superstructure of slab bridge is usually designed as irregular shaped structure. Irregular slab bridges, as a kind of typical space structures, are always in multiaxial stress state and display complex mechanical behavior. So, precise analysis theory and practical simplified calculating method are necessary to be improved. In this paper, a simple-supported irregular bridge, Wayaoxi Bridge, located in Tuokou town, Guizhou Province, is taken as background project. The irregular slab bridge of Wayaoxi is simulated by three numerical finite element models, namely，shell model, solid model and space beam grillage model. Furthermore, test of bridge in-site is carried out. By comparing the results of numerical calculation and bridge test, mechanical behavior and dynamic characteristic of the irregular slab bridge under highway design load can be obtained. Applicable conditions have been presented through the analysis of computational accuracy of each finite element modal. Finally, the conclusions of this research can be applied to the calculation, design and construction of this type of irregular slab structures.

KEYWORDS

Irregular bridge, Reinforced concrete bridges, Finite element modal.

INTRODUCTION

Slab bridge is commonly used in small span bridges, with many advantages such as small building height, concise configuration, simple templates. With the development of transportation, especially the increasing number of highways, urban interchanges and viaducts, irregular shaped slab bridges has been more widely used. Irregular shaped slab bridge not only meets the road alignment, building clearance and driving comfort requirements, but also has good architectural aesthetic effect. However, irregular shaped slab bridge has more complex stress state than ordinary linear orthogonal bridge, the spatial analysis and supports disposing are difficult and important in such bridges, so general concern are given by lots of engineers. In 1989, the professor Xia Gan proposed grid simulation and impact surface method to calculate irregular shaped slab structure, and established the corresponding computing program. Currently, many scholars have conducted theoretical and experimental research of irregular shaped slab structures, but its theory and practical algorithm still needs further study. In this paper, Wayaoxi bridge, located in Guizhou Province, is taken as research object, and it is simulated by plate elements model, solid elements model and space grillage model. Finite element numerical calculation and bridge test in-site are conducted to analyze the irregular slab bridge. Then, by comparing numerical calculation and bridge test results, the mechanical behavior and dynamical property of irregular slab bridge

under highway design loads are got. Further, application conditions of each simulation modal can be proposed by the analysis of the accuracy of three computing models, which can provide theoretical basis and practical reference for the calculation of similar irregular slab structures.

ENGINEERING BACKGROUND AND FINITE ELEMENT MODEL

Project Overview

Wayaoxi bridge is located on the left bank tributary of Qingshui river, the outlet of Wayao River of the rehabilitation road from Lantian to Wengdong, in Guizhou reservoir area of Tuokou hydropower station. Class of loading is on highway-Ⅱ level. Bridge structure is arranged as 13m situ reinforced concrete irregular slab + 3 × 20m situ reinforced concrete simple supported T girder + 13m situ reinforced concrete irregular slab, and total length of the bridge is 93.62m. Standard span of the situ reinforced concrete irregular slab span is 13m with beam length of 12.92m and beam height of 0.7m.There are side ribs of 0.65m width and 0.75m height on each side of the irregular slab, with a cantilevered slab of 1.0m length outside each side rib. The general arrangement of this bridge is shown in Figure 1, the cross section of irregular slab is shown in Figure 2 and its plane layout is shown in Figure 3,

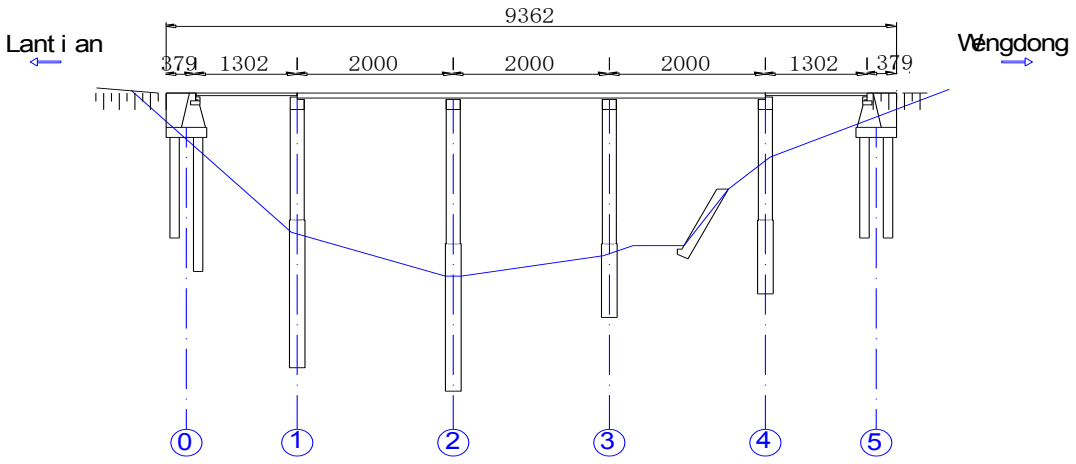

Figure 1 Bridge facade layout (dimension unit: cm)

Figure 2 Cross section of irregular slab (dimension unit: cm)

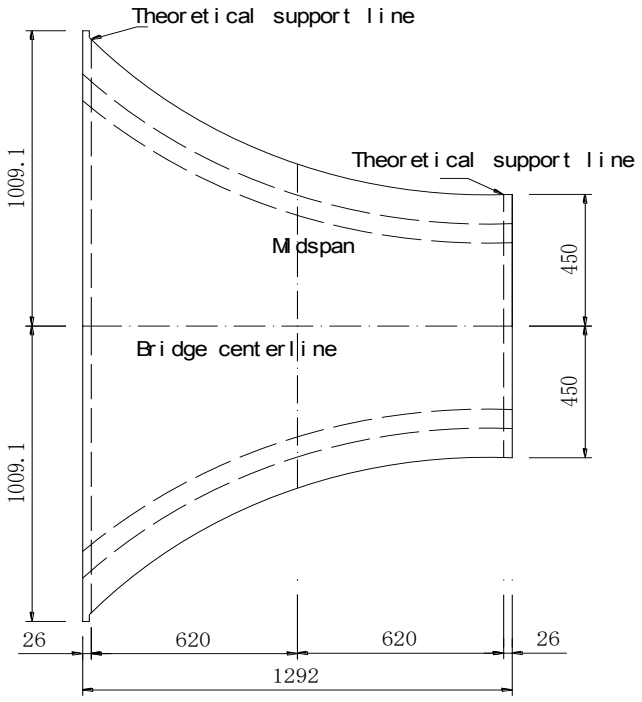

Figure 3 plane layout of irregular slab (dimension unit: cm)

Beam Grid Finite Element Model

The internal forces (axial force, shear, moment and torque) of slab superstructure are in two-dimensional distribution state, which are more complex than one-dimensional beam. Beam grid method will make bending and torsional stiffness which distributed in each segment of the slab concentrated in the adjacent equivalent beam grids, that means the longitudinal stiffness of the slab is focused on the longitudinal beam grid, the transverse stiffness of the slab is focused on the transverse beam grid, in order to achieve the equivalent slab structure. Beam grid method is to reduce the dimension of internal forces distribution and simplify the structure, it makes the concept of the force distribution clear, and the stress analysis and design of reinforcement easy for practical engineering structures.

The width of irregular slab varies gradually in the plane, so gradient beam grid is used to simulate the irregular slab bridge. However, section properties along the longitudinal grillage member changes. Longitudinal beam grid members are arranged as shown in Figure 4. The flange slab and ribs are divided into longitudinal beam grid members, intermediate slab is divided into five stringers, the entire beam grid model has nine stringers, cross-sectional width of the beam gird changes gradually along the beam axis. Horizontally, the sheet bends around its own centroid, the rod member 1-2 and 8-9 approximately use the average thickness of the flange slab, rod member 2-3,3-4,4-5,5-6,6-7 and 7-8 approximately use the intermediate slab thickness. For a solid slab, the moment of inertia and torque of longitudinal and transverse beam grid are to be calculated according to the width of each slab member.

The bending moment of inertia of unit slab width: $I = \frac{d^3}{12}$ (d is the slab thickness)

The torsion constant of unit slab width: $c = \frac{d^3}{6}$ (d is the slab thickness)

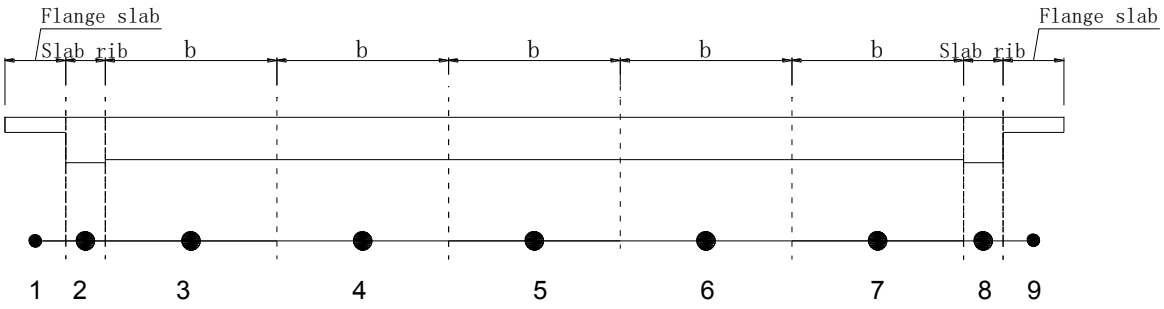

Figure 4 The division of longitudinally beam grid member

Element division and calculation modal are shown in Figure 5. Every node of each beam element has three directions of translational movement and three directions of rotational displacement, so each node has six degrees of freedom.

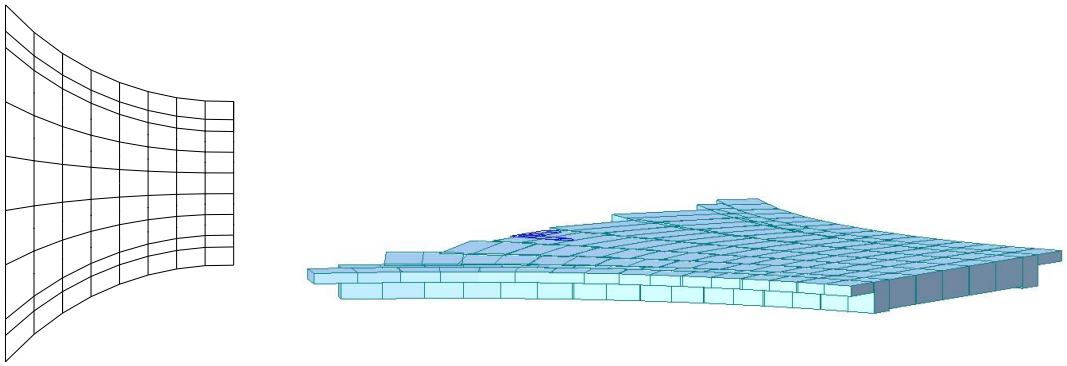

Figure 5 The division of irregular slab elements and beam grid computing model

Shell Finite Elements Model

The thickness of irregular slab is 0.7m, far less than its longitudinal length and transverse width, so this slab bridge can be simulated by shell elements. There are two types of shell elements, thin plate and thick plate, can be used in Midas civil. In this paper, quadrilateral thick plate is choosen to model the irregular slab bridge, shell finite element model and elements division are shown in Figure 6.

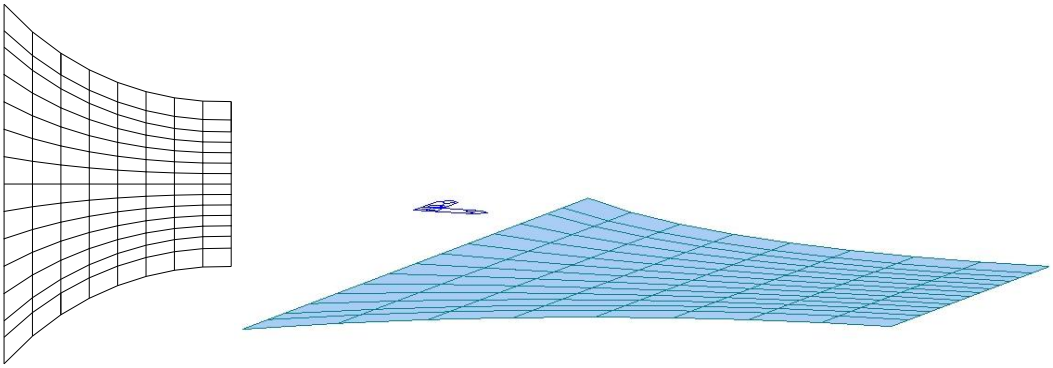

Figure 6 The division of irregular slab elements and shell computing model

Solid Finite Element Model

In this paper, hexahedral three-dimensional solid elements are used to analyze the stress state of the irregular slab. The degrees of freedom of solid elements are based on the global coordinate system, each element has eight nodes, each node has three directions of translational displacement. The three-dimensional finite element model of irregular slab and elements division are shown in Figure 7.

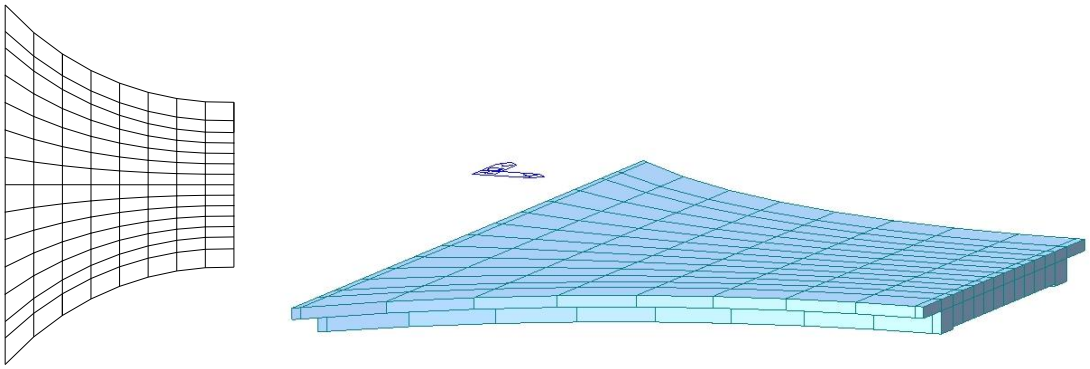

Figure 7 The division of irregular slab elements and solid computing model

ANALYSIS OF RESULTS

The beam grid model, whose concept is clear and model is simple, can better reflect the main mechanical characteristics of the irregular slab bridge structure, and is convenient to be used in the design. Shell Model and solid model can simulate the mechanic behavior of the actual structure more accurately, especially the local stress behavior. Based on the three computing model above, the static and dynamic characteristics of irregular slab bridge under design load of highway-Ⅱ level are got. Auto load consists of lane load and vehicle load, and overall calculation of bridge structure must use lane load in accordance with the specification. Lane load includes uniform load and concentrated load, and the uniformly distributed load qk and concentrated load Pk of highway-Ⅱ are 0.75 times of that of load of highway-Ⅰ level.

The following conditions are taken for the accuracy comparation of the results of the three computing models:

-Case 1: self-weight load;

-Case 2: Load of Highway-Ⅱarranged along the midline of irregular slab + both sides of sidewalk fully covered;

-Case 3: Load of Highway-Ⅱarranged along the edge lane of irregular slab + both sides of sidewalk fully covered ;

Case 1 is mainly used to contrast the differences of results of three computing model under self-weight load. Ensuring the reliability of results of various computing models under self-weight, is a basic promise of proving beam grid, shell and solid models are static equivalent with the actual structure.

Case 2 and 3, respectively, simulate the stress states of irregular slab subjected to symmetric load and eccentric load, the difference of three models under lane load is compared. Bridge test follows the principle that the test load effect is equivalent to design load effect. The deflection and stress of bridge in each test condition are measured, finally the comparison, analysis and verification of each calculation methods are conducted.

Comparative Analysis of Deflection

When structure is simulated by beam elements, shell elements and solid elements, displacement results are firstly obtained by finite element method, internal forces and stresses are obtained by further calculation based on displacement. Therefore, if the displacements of finite element model agree with the actual displacements, it indicates that the finite element model can accurately simulates the stiffness of actual structure, and can more accurately simulates the mechanical behavior of the actual structure. The calculated displacements in various conditions are shown in Table 1. Since the displacements of irregular slab under eccentric loads may reflect torsional effect of slab, the displacements of both sides under eccentric loads are listed in the table.

The results show that the displacement values under self-weight obtained by three computing methods are similar, the distribution of displacements is basically the same, but the displacement of shell model is largest among these three models.

Table 1 Displacements of finite element models under various conditions

	Finite element model	The displacement distribution	Max（mm）	The maximum position	The Maximum test value in midspan
Self-weight	Bean gird model		6.7	Midspan of edge beam	/
	Shell model		7.3	Midspan of side slab	
	Solid model		6.6	Midspan of the edge	
Symmetric load	Bean gird model		1.2	Midspan of Centre beam	1.0mm
	Shell model		1.2	Midspan of side slab	
	Solid model		1.3	midspan	

Eccentric load	Bean gird model		1.5（1.0）	Midspan of edge beam in the loading side（Midspan of edge beam in the unloading side）	1.4mm（Midspan in the loading side）
	Shell model		1.5（1.0）	Midspan of side slab in the loading side（Midspan of side slab in the unloading side）	
	Solid model		1.9（1.0）	Midspan of solid in the loading side（Midspan of solid in the unloading side）	

Comparative Analysis of Stress

Concrete has low tensile strength, the bottom of simple supported slab bridge is in tension under self-weight or external loads. By making comparation of measured stress values and theoretical stress values of bottom slab, the working condition of bridge can be judged, so stress nephograms and maximum stress of bottom slab under different conditions are listed in Table 2. Further comparative analysis of stress distribution law of each finite element model can be obtained. Stress measuring point layout is shown in Figure 8.

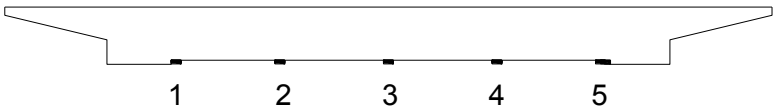

Figure 8 Measuring points layout of strain in cross section of midspan

Table 2 Stress of finite element models under various conditions

	Finite element model	stress distributing graph	Max（MPa）	The maximum position	The Maximum test value
Self-weight	Bean gird model		5.37	Midspan of edge beam	/
	Shell model		4.87	Midspan of edge rib	

	Solid model		4.81	Midspan of the edge entity	
symmetric load	Bean gird model		1.08	Midspan of center beam	1.10MPa（No3 measuring point）
	Shell model		0.90	Midspan of centerline	
	Solid model		1.07	Midspan of centerline	
eccentric load	Bean gird model		1.44	Midspan of side beam	1.42MPa（No.1 measuring point）
	Shell model		1.08	Midspan of edge rib	
	Solid model		1.47	Midspan of edge rib	

Comparison of Natural Frequencies

The mode of vibration and frequency can be calculated by three finite element models and the results of three models are shown in Table 3. Three kinds of model calculation results can show that the first mode shape are vertically symmetric and the frequency values are substantially the same, which indicates that three models can simulate stiffness of the irregular slab well.

According to the actual conditions, jumping test is adopt to conduct dynamic load test. In the case of t he bridge without any obstacles, the test vehicle crosses over a barrier of 3cm to 15cm and stop imme diately, so that the bridge produces damped free vibration, and the curve of vibration attenuation is rec orded. Test measured time-history curve and spectrum analysis diagram are shown in Figure 9.

Dynamic load test results show that: the jumping test on this irregular slab bridge is ideal, damped free vibration waveform is relatively intact and the first order of vertical bending vibration frequency can be accurately identified. Test frequency of test span is larger than its theoretical frequency, which shows that the integral rigidity of the irregular slab bridge meets the design requirements.

Table 3 The theoretical value and test value of natural vibration characteristics of irregular slab

Finite Element Model	Mode shape	Theoretical frequency value	Measured frequency value
Grillage model		6.9 Hz	9.5 Hz
Shell Model		6.9 Hz	
Solid Model		7.2 Hz	

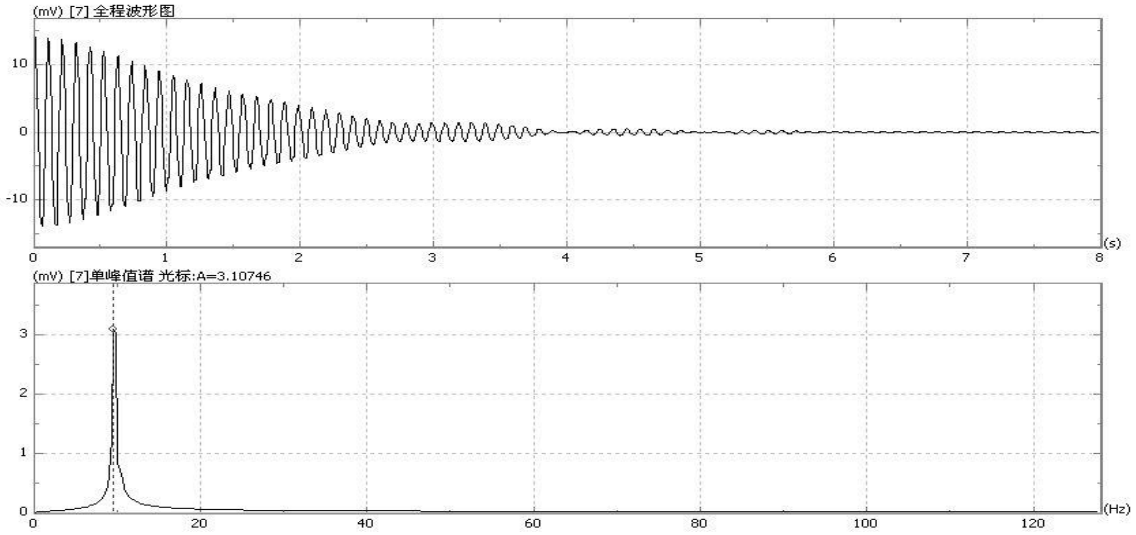

Figure 9 The schedule signal and spectrum analysis of irregular slab bridge in bump test

Table 4 The dynamic characteristics of irregular slab

	Finite Element Model	Mode shape	Theoretical frequency value
The second Order vibration	Grillage model		12.0Hz
	Shell Model		13.2Hz

	Solid Model		12.9Hz
The third Order vibration	Grillage model		16.2Hz
	Shell Model		25.7Hz
	Solid Model		26.6Hz

CONCLUSION

All the three calculation models can simulate mechanical characteristics and deformation conditions of irregular slab bridge under each working conditions well, and can also reflect the dynamic behaviors of the structure exact ly.

Under its self-weight, the irregular slab bridge is in biaxial stress state, the transverse bending moment, less than the longitudinal bending moment, but can't be neglected. An arrangement of longitudinal reinforcement is neces sary, and the arrangement of transverse reinforcement is also required.

Under lane load, whether symmetric load or eccentric load, the irregular slab is in biaxial stress state, so the reinf orcement should coincide with the mechanical characteristics. By calculation, longitudinal main steel bar is not o nly need to arrange, transverse reinforcement is also need to be arranged to bear the transverse bending moment generated by vehicle load.

The first order shape of the irregular slab is vertically symmetric and the shape obtained by three models are the same. The second order shape and the third order shape obtained from three different models are also the same, it can be found that all the models can reflect the dynamic characteristics well.

Under various working conditions, stress calculated by beam grid method is larger than the other models, it mean s that the reinforcement arranged as the results of beam grid model can be safer than the other computing models , and beam gird method is the most convenient method in fact.

Performance under Seismic Loading

PERFORMANCE-BASED PLASTIC DESIGN OF SELF-CENTERING STEEL BRACED FRAME

Songye Zhu[1], Can-Xing Qiu[1]

[1]Department of Civil and Environmental Engineering, The Hong Kong Polytechnic University, Hong Kong

This study proposes a performance-based seismic design (PBSD) method for steel braced frames with novel self-centering (SC) braces that utilizes shape memory alloys (SMA) as a kernel component. The presented PBSD method is essentially a modified version of the performance-based plastic design. A few concentrically braced frames with SC braces are designed as examples to illustrate the efficacy of the proposed design method. The seismic performance of the designed frames is examined at various seismic intensity levels. Results of nonlinear time-history analyses indicate that the designed SC braced frames can successfully achieve the prescribed performance objectives at three seismic hazard levels.

ABSTRACT

In modern seismic design, damping devices are often used to dissipate seismic energy and therefore enable a control of the structural response to earthquake ground excitation. As a result, the member section sizes or the amount of reinforcement in a structure with dampers may be reduced from those without dampers. Although both designs may be made as equivalent in terms of their performances under design earthquakes, their capacities in resisting collapse under the worst credible earthquake scenarios could be different, and there is little information from the literature that addresses this concern. In this paper, the collapse-resistance capacities of RC frames designed for different seismic hazard levels with and without dampers are calculated through a collapse fragility analysis using an incremental dynamic analysis approach, and the results are compared. On this basis, a proposal is put forward for the purpose to enhance the collapse-resistance capacities of structures with dampers in high seismic hazard levels. The effectiveness of the proposed enhancement is demonstrated.

KEYWORDS

RC frame, seismic design, damping effect, incremental dynamic analysis, collapse fragility analysis.

INTRODUCTION

Conventional seismic design of reinforced concrete structures usually adopts larger member sizes or more reinforcement in order to achieve a desired seismic performance. With the introduction of seismic dampers, which help dissipate seismic energy and thus reduce the seismic response, it becomes possible to make the structure lighter and with less steel reinforcement. The use of dampers also allows for a control over the dynamic response of the structures. The subject of vibration control in seismic design has been studied for decades as it has many advantages, such as an explicit energy dissipation mechanism and a controllable seismic response reduction effect (Soong and Dargush 1997; Symans and Constantinou 1998). In recent years significant progresses have been achieved in terms of the development of many kinds of dampers, for example metal dampers, friction dampers, fluid viscous dampers and viscoelastic dampers.

Among these dampers, the viscous damper has been widely used as passive energy dissipation device in newly-built structures or in the seismic retrofit of existing structures. In the case of retrofitting with viscous dampers, the retrofitted structure is always expected to have better seismic performance than the original structure (Uriz and Whittaker 2001). However, the situation is much more complicated in the case of a new design. When viscous dampers are used in the design of new buildings, the main structure will be proportioned on the basis of reduced earthquake actions due to the added damping effect. According to the practice in China, the main structure of a building with the addition of viscous dampers is usually designed with a reduced level of seismic intensity by half a degree. This procedure results in smaller section sizes and/or less amount of reinforcement in the main structure than that of conventional seismic design without dampers. In theory, both designs are considered to be equivalent as far as the design earthquake hazard level is concerned.

As a matter of fact, earthquake is a natural hazard with a great degree of uncertainty. Among many strong earthquakes that occurred in China, the actual earthquake intensity in the epicentric regions has usually been much higher than the seismic hazard levels set by the seismic design code (Lu *et al*. 2012). Taking the WenChuan earthquake for example, the seismic hazard levels in the affected regions are mostly 6 or 7 degree, but the actual intensity in the epicentric regions was between 8 to 11 degree. Many structures collapsed because of the unexpected strong earthquakes. Therefore, considering the large uncertainty involved, it is important for structures to have a sufficient reserve capacity so as to withstand a plausible stronger earthquake without a catastrophic collapse, and this philosophy should understandably extend to structures designed with dampers.

There is little information in the literature regarding the comparative collapse-resistance capacities of structures designed without and with the consideration of the added damping effects when both are designed for the same seismic design requirements. The extent to which the effect of viscous dampers might contribute to the collapse-resistance capacity of the structures has not been properly investigated before. In the present paper, the collapse-resistance capacities of reinforced concrete frames designed in different seismic hazard levels with and without dampers are compared. The comparison uses a collapse fragility analysis method based on the incremental dynamic analysis (IDA) approach (Vamvatsikos and Cornell 2002; Zareian and Krawinkler 2007).

METHODOLOGY

The structural fragility analysis carried out in the present study is mainly based on IDA. The details of the analysis procedure have been presented in (Miao *et al*. 2012). The key steps involved in the fragility analysis include construction of the numerical model for the structure, selection of the earthquake ground motions, selection of the earthquake intensity measure, and selection of the collapse criterion.

The IDAs are implemented by using THUFIBER (Lu *et al*. 2013), a fiber-beam-element package that was developed based on the finite element software MSC.MARC. Material-based constitutive models and an elemental deactivation (deletion) technique are employed in THUFIBER to simulate the structural nonlinear behaviour and the total failure of individual members. The effectiveness of THUFIBER in the simulation of the nonlinear behaviour of reinforce concrete frames under strong earthquake ground motions has been verified by a variety of examples (Lu *et al*. 2013).

A set of far-field ground motions recommended by ACT-63 project (FEMA 2009), combined with the widely used EI-Centro ground motion, are selected as the basic input earthquakes. The spectral acceleration at the structural fundamental period ($S_a(T_1)$) is selected as the intensity measure of ground motions.

In the time-history analysis, if any major structural components drop vertically by more than 1 meter, the structure is considered to have reached collapse. The choice of 1 meter as the collapse criterion is somewhat arbitrary; however trial analyses have indicated that when a vertical displacement reaches this value the structure is generally in an unstable state, so for simplicity 1 meter is adopted as the collapse criterion.

The collapse fragility curve represents a relationship of the probability of structural collapse to the variation of the earthquake intensity. On a fragility curve, the ordinate value of the point corresponding to the anticipated maximum earthquake intensity is regarded as the collapse probability of the structure under the maximum considered earthquake. The ATC-63 project proposes that if the collapse probability of a structure under the maximum considered earthquake is less than 10%, the structure is deemed to satisfy the objective of "no collapse under the maximum possible earthquake".

In order to evaluate the comparative collapse-resistance capacities of different structures, the ATC-63 project proposes the use of the Collapse Margin Ratio (CMR) as an indicator. CMR is defined as the ratio of the actual collapse resistance of the structure to the earthquake intensity of the specified collapse-prevention level (maximum considered earthquake). Thus, CMR is conceptually similar to a safety factor (Tang *et al*. 2011). If we take the actual average collapse resistance of the structure, represented by the ground motion intensity under which there is a 50% chance of collapse, as $S_a(T_1)_{50\%collapse}$, and the ground motion intensity of the maximum considered earthquake as $S_a(T_1)_{MCE}$, the CMR corresponding to the maximum considered earthquake is calculated as:

$$CMR_{MCE} = S_a(T_1)_{50\%collapse} \big/ S_a(T_1)_{MCE} \tag{1}$$

NUMERICAL MODELS

A series of six-story and nine-story RC frames with Site Class III, Seismic Design Group I and Seismic Design Categories C according to the Chinese Code for Seismic Design of Buildings (GB50011-2010) (2010) are designed adopting conventional seismic design method (denoted as 'conventionally designed frame' or simply 'conventional design'). Three different design seismic intensity levels are considered, namely 7.5, 8 and 8.5 degree, or moderate, moderate-to-strong, and strong levels. The corresponding design peak ground accelerations (PGA) are 0.15g, 0.2g and 0.3g, respectively.

Parallel to the above conventional design, each individual frame is also designed with consideration of added fluid viscous dampers (denoted as 'damper-designed frame', or DDF) to form comparative pairs. For the

conventionally designed frames, the three six-storey ones are designated as KZ6-7.5, KZ6-8 and KZ6-8.5, respectively, and the three nine-storey ones are KZ9-7.5, KZ9-8 and KZ9-8.5, respectively. Their respective damper-designed counterparts are designated as JZ6-7.5, JZ6-8 and JZ6-8.5 (six-storey), and JZ9-7.5, JZ9-8 and JZ9-8.5 (nine-storey), respectively. The last number in the above labels, i.e. 7.5, 8 and 8.5, indicates the design seismic intensity levels.

All frames have the same plan layout, as shown in Fig. 1(a). The elevation views of the 6-story and 9-story frames are shown in Fig. 1(b) and (c). All frames are designed with the same standard values of the design gravity loads, including: floor dead load 4.5 kN/m^2; floor live load 2.5 kN/m^2; roof dead load 6.0 kN/m^2; roof live load 2.0 kN/m^2; snow load 0.5 kN/m^2, load along length of exterior wall 4 kN/m; load along length of interior wall 2 kN/m.

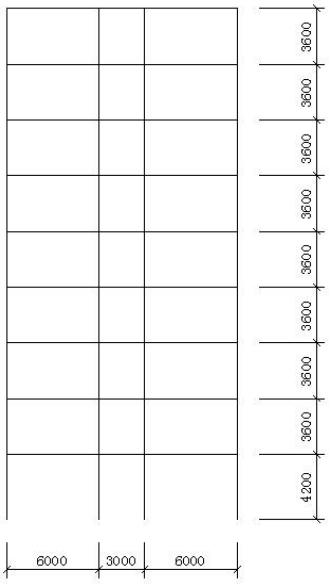
（b）Elevation of 6-story frames



（c）Elevation of 9-story frames

Figure 1 layout and dimentions of frames (unit: mm)

All frames are designed according to the Chinese seismic design code using a general-purpose design software package (PKPM). The member cross-section sizes and the material strengths are shown in Table 1. The cross-section sizes of columns are determined by the requirement to satisfy the maximum inter-storey drift under frequent earthquakes, which is 1/550. This also enables all frames to be comparable with each other. As can be seen from the summary shown in Table 2, all frames exhibit more or less the same maximum inter-storey drift under the specified frequency earthquakes.

A previous study (Tang *et al*. 2009) suggests that the collapse resistance of an RC frame is largely determined by the axial compression ratios of bottom columns. With this in mind, in the present study the member sizes of a damper-designed frame (DDF) are made the same as its conventional counterpart so that the collapse-resistance capacities of the DDFs are not disadvantaged from the outset (due to the reduction of member sizes). The detailed reinforcement in a DDF is then designed with a reduced design seismic intensity level by half a degree.

In other words, a DDF has the same structural member sizes with its conventional counterpart in this study, but the details of the main steel reinforcement between each pair are different. It should be noted that the seismic design also includes the detailed design of transverse reinforcement (stirrups); however to avoid complication in the comparisons the transverse reinforcement is kept the same between a DDF and its conventional counterpart.

Table 1 Cross-section sizes（width × depth）and material strengths

Frame Numbers	KZ6-7.5	KZ9-7.5	KZ6-8	KZ9-8	KZ6-8.5	KZ9-8.5
Column sizes of storey 1 to 3 (mm× mm)	500×500	550×650	600×600	600×700	750×750	800×900
Column sizes of storey 4 to 6 (mm× mm)	450×450	550×550	500×500	600×700	650×650	800×850
Column sizes of storey 7 to 9 (mm× mm)	--	550×550	--	600×700	--	800×850
Outer beam sizes (mm× mm)	250×500	250×500	300×550	300×550	400×650	400×700
Inner beam sizes (mm× mm)	250×450	250×450	300×500	300×500	400×600	400×600
Concrete strength of storey 1 to 3	C30	C30	C30	C40	C30	C40
Concrete strength of storey 4 to 6	C30	C30	C30	C30	C30	C40
Concrete strength of storey 7 to 9	--	C30	--	C30	--	C30
Longitudinal rebar strength	HRB400					
Stirrup strength	HPB300					

Note: C30 has a characteristic compressive strength of 20.1 MPa; C40 is 26.7 MPa
HRB400 has yield strength of 400 MPa; HPB300 is 300 MPa

Table 2 Largest column axial compression ratio and maximum inter-story drift ratio under frequent earthquake

Frame Numbers	KZ6-7.5	KZ9-7.5	KZ6-8	KZ9-8	KZ6-8.5	KZ9-8.5

5	2VD1	4VD1	2VD1	3VD1	4VD2	10VD3
4	2VD1	4VD1	2VD1	3VD1	4VD2	10VD3
3	2VD1	6VD1	2VD1	3VD1	4VD2	10VD3
2	3VD1	6VD1	2VD1	3VD1	4VD2	10VD3
1	3VD1	6VD1	2VD1	3VD1	4VD2	10VD3

Note: VD1(viscous damper 1) C=700kN/(m/s)$^{0.4}$, α=0.4
VD2(viscous damper 2) C=1000kN/(m/s)$^{0.3}$, α=0.3
VD3(viscous damper 3) C=1000kN/(m/s)$^{0.4}$, α=0.4

The desired additional damping ratio provided by dampers is calculated based on the consideration that the seismic responses of the DDFs would be reduced in equivalence to a reduction of the earthquake intensity by half a degree. Then a necessary number of nonlinear viscous dampers are added to the frame to actually achieve the desired additional damping ratio. Dampers in diagonal braces are uniformly arranged along the height of frames. The arrangements of dampers are shown in Table 3. The mechanical behavior model of nonlinear viscous dampers is as follows:

$$F = C \cdot V^{\alpha} \tag{2}$$

where F is the damping force, V is the relative axial velocity between the two ends of viscous damper, C is damping coefficient, and α is damping exponent ($0<\alpha<1$).

Table 4 T_1 and $S_a(T_1)_{MCE}$ for all frames

Frame Numbers	KZ6-7.5 JZ6-7.5	KZ6-8 JZ6-8	KZ6-8.5 JZ6-8.5	KZ9-7.5 JZ9-7.5	KZ9-8 JZ9-8	KZ9-8.5 JZ9-8.5
Fundamental vibration period T_1 (s)	1.20	0.93	0.65	1.43	1.18	0.81
Ground motion intensity of the maximum considered earthquake $S_a(T_1)_{MCE}$ (g)	0.32	0.52	0.95	0.28	0.42	0.78

The IDAs for all frames are conducted in the lateral direction (Y direction in Fig.1a). The analytic models are constructed in accordance with the design details, as shown in Figs 2 and 3. The numbers in Figs 2 and 3 represent the areas of reinforcing bars on each side for columns and on the top and bottom side for beams. 100% dead load and 50% live load within the shaded area in Fig.1a are assigned to each 2D frame model. In the analysis of the DDFs, the damping coefficient C induced by the dampers on a single frame is determined by proportion to the number of frames. The damping ratio α remains unchanged. The structural fundamental vibration period T_1 of all frames is shown in Table 4. Note that the DDFs is assumed to have approximately the same T_1 as its conventional counterpart as the dampers do not add direct stiffness to the main structure and the effect of damping on T_1 is relatively small. For the three different design seismic intensity levels, the corresponding elastic design pseudo acceleration spectrum for the maximum considered earthquake specified in the Chinese seismic design code is used to calculate the respective ground motion intensity of the maximum considered earthquake $S_a(T_1)_{MCE}$ in this study (Table 4).

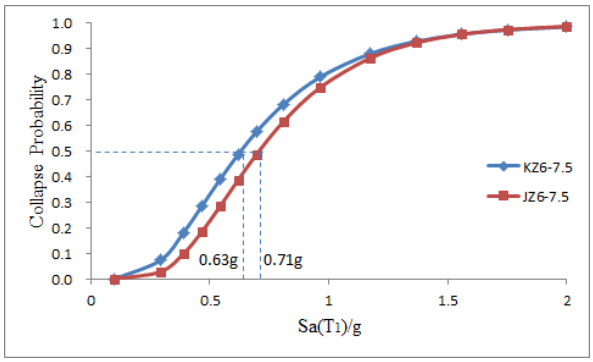
RESULTS AND DISCUSSION

The Results of IDAs

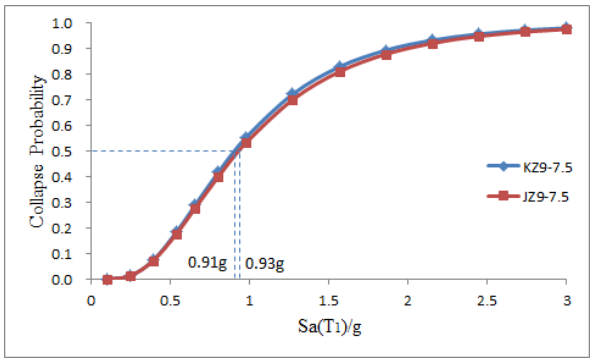
IDAs are carried out for all cases and the collapse probabilities of each frame at different earthquake intensities are obtained. The relationship between collapse probability and earthquake intensity is found to follow closely the lognormal distribution, therefore the collapse fragility curves are constructed via lognormal distribution curve fitting. Fig. 4 shows the comparison of fragility curves between the conventional seismic design frames (KZ-) and the DDFs (JZ-).

Based on these curves, the probabilities of structural collapse under the respective maximum considered earthquakes can be obtained, and the results are listed in Table 5 and 6. The collapse probabilities for all frames under their maximum considered earthquakes are less than 10%, so all frames have achieved the requirement of ‘no collapse under maximum considered earthquakes’.

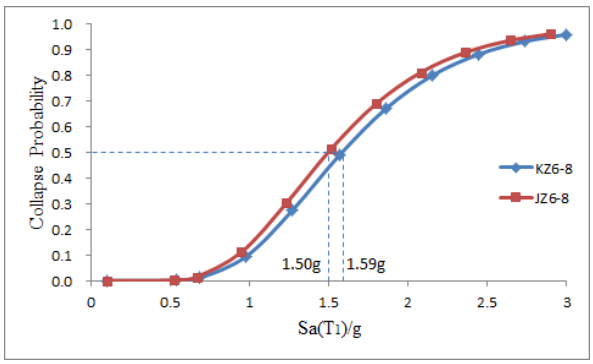
The effect of using dampers on the collapse probability does not exhibit simple trends and the relative fragility curves vary in different design cases. To calculate the CMRs, we can identify the values of $S_a(T_1)$ corresponding to 50% probability of collapse, which represents the collapse resistance capacity. Subsequently, the CMRs can be calculated using the formula in Eq. 1. The CMRs are also listed in Table 5 and 6 for the 6-storey and 9-storey frames, respectively.



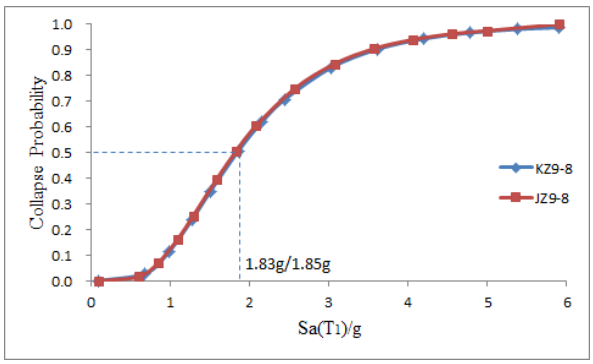
(a) KZ6-7.5 and JZ6-7.5



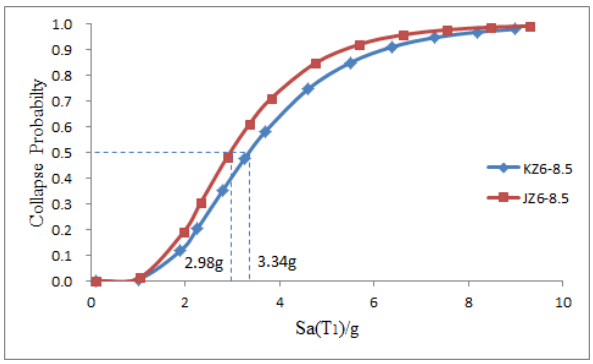
(b) KZ9-7.5 and JZ9-7.5



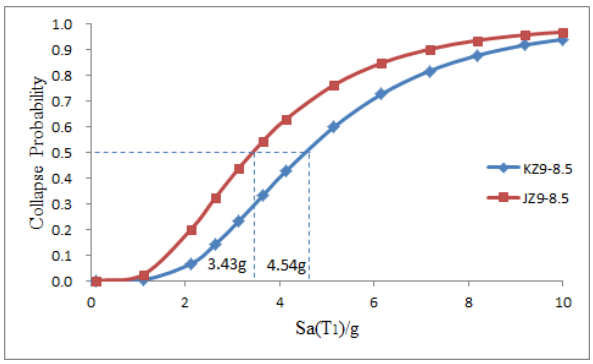
(c) KZ6-8 and JZ6-8



(d) KZ9-8 and JZ9-8



(e) KZ6-8.5 and JZ6-8.5



(f) KZ9-8.5 and JZ9-8.5

Figure 4 Comparison of fragility curves between conventional and damper-designed frames

Table 5 Collapse ratio and CMR under maximum considered earthquake for 6-story frames

Frame numbers	KZ6-7.5	JZ6-7.5	KZ6-8	JZ6-8	KZ6-8.5	JZ6-8.5
CR_{MCE}	9.13%	3.84%	0.14%	0.23%	0.49%	0.76%
CMR	1.97	2.22	3.09	2.91	3.50	3.13

Table 6 Collapse ratio and CMR under maximum considered earthquake for 9-story frames

Frame numbers	KZ9-7.5	JZ9-7.5	KZ9-8	JZ9-8	KZ9-8.5	JZ9-8.5
CR_{MCE}	2.06%	2.06%	0.22%	0.23%	0.0%	0.0%
CMR	3.27	3.35	4.45	4.40	5.84	4.41

Based on the results shown above, the following observations can be made:

(1) For the design level of 7.5 degree cases, the conventional design results in higher collapse probability under the maximum considered earthquakes and lower CMRs than DDFs, indicating that the damper-designed frames have higher collapse-resistance capacity than the conventional frames.

(2) For the design level of 8 degree cases, the 6-story DDFs appear to be higher probability to collapse under maximum considered earthquakes and have lower CMR than the conventional frames. The 9-story DDFs have almost the same CMR and collapse probability as their conventional counterparts. This tends to indicate that for the design level of 8, the damper-designed frames have not introduced noticeable change in terms of the collapse-resistance capacities.

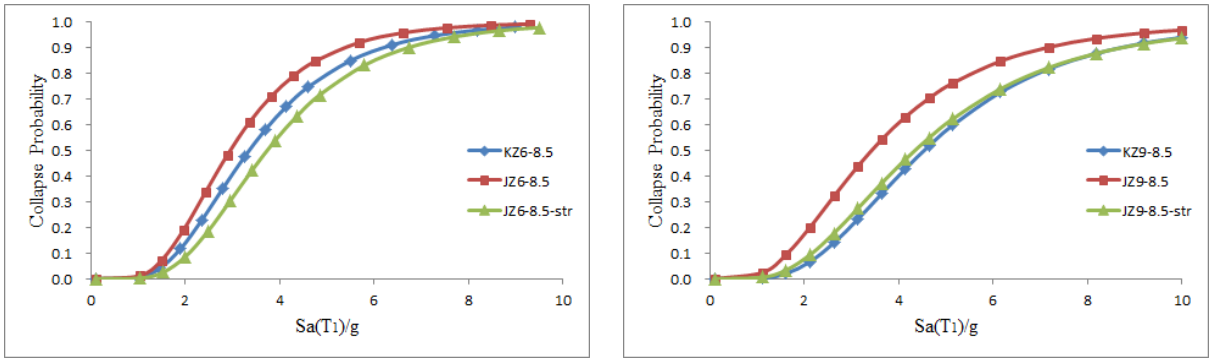
(3) In the design level of 8.5 degree cases, the conventional frames have markedly lower collapse probability under the maximum considered earthquakes and higher CMR values than the DDFs. Considering the observations made in (1) and (2) above, it appears to be clear that for higher design intensity levels, the use of dampers will reduce the collapse-resistance capacity of the frames as compared to the conventionally designed frames.

Enhancement of the Collapse-resistance Capacity

The calculated results under 23 earthquakes show that failure of bottom columns is the main reason that causes the collapse of the frames in both conventional and damper-designed frames. Therefore, it is meaningful to examine the effect of strengthening the bottom columns on improving the collapse-resistance capacity.

For simplicity, the reinforcing bars in the bottom columns of the damper-designed JZ6-8.5 and JZ9-8.5 are strengthened to be the same as that of conventional frames KZ6-8.5 and KZ9-8.5, while the reinforcement in the remaining storeys are unchanged. The two strengthened DDF cases are designated as JZ6-8.5-str and JZ9-8.5-str respectively. IDAs are implemented for these two cases and fragility curves are constructed. The fragility curves for the two groups of conventional, DDF, and DDF-strengthened 6-storey and 9-storey frames, respectively, are compared in Fig. 5.

Based on the fragility curves, the collapse probabilities of JZ6-8.5-str and JZ9-8.5-str under maximum considered earthquakes are obtained, and subsequently CMRs are calculated. The results are shown in Table 7.



(a) 6-story (b) 9-story

Figure 5 Comparison of collapse probability among conventional, DDF, and strengthened DDF frames

Table 7 Structural collapse probability and CMR values under maximum considered earthquake of strengthened DDFs

	JZ6-8.5-str	JZ9-8.5-str
CR_{MCE}	0.14%	0.08%
CMR_{MCE}	3.92	5.59

Examining the results in Table 7 with comparison to those in Table 5, the collapse probability of JZ6-8.5-str under maximum considered earthquake is reduced to 0.14% from 0.76% for JZ6-8.5, while the CMR of

JZ6-8.5-str is 3.92, which is 25.2% higher than the CMR of JZ6-8.5. This shows that strengthening the reinforcement in the bottom columns can significantly enhance the collapse-resistance capacities of the 6-story damper-design frames. Furthermore, the strengthened JZ6-8.5-str also exhibits even a higher collapse-resistance capacity than the conventional counterpart KZ6-8.5.

For the 9-storey cases, the collapse probability of JZ9-8.5-str under maximum considered earthquake is reduced to 0.08% from 0.49% for JZ9-8.5, and the CMR of JZ9-8.5-str is 5.59, which is 26.7% higher than that of JZ9-8.5. This shows that strengthening the reinforcement in the bottom columns in equally effective in enhancing the collapse-resistance capacity of the DDF in the 9-storey cases as well. Comparing to the conventional case of KZ9-8.5, the collapse-resistance capacity of JZ9-8.5-str is also much improved from the position of JZ9-8.5 and is very close to that of KZ9-8.5.

In summary, for the damper-designed frames in high design seismic levels, strengthening the reinforcement in the bottom columns can significantly enhance their collapse-resistance capacities with an increase of the CMRs by an order of 25%. The collapse-resistance capacities of the partially strengthened damper-designed frames can be considered as equal to (could be even better than) their conventional counterparts.

CONCLUSIONS

In this paper, the collapse resistance of reinforced concrete frames designed with the consideration of added damper effects (referred as DDF) is evaluated with comparison to the conventional seismic design without incorporating dampers. Representative 6-storey and 9-storey frames are designed as DDF and conventional designs for three different seismic design hazard levels of 7.5, 8 and 8.5 degree, respectively. The collapse-resistance capacities of both designs are then calculated with a collapse fragility analysis using an incremental dynamic analysis approach. The following general conclusions can be made:

(1) Both the DDF and conventional designs can achieve the design objective of withstanding the maximum considered earthquakes without collapse (probability of collapse below 10%).

(2) The DDF cases at a design seismic level of 7.5 degree exhibit higher collapse-resistance capacities than their conventional counterpart, this situation tends to reverse in the cases with higher design seismic levels of 8.0 and 8.5 degree.

(3) Almost all of the results suggest that failure of the bottom columns is the primary cause of the collapses, and this is particularly true for the DDF cases. Therefore partially strengthening the DDF frames by increasing the reinforcement in the bottom columns appear to be a logical choice in enhancing the collapse resistance of the DDFs especially for the higher design seismic levels.

(4) It is demonstrated that for the DDF cases in high design seismic levels, strengthening the reinforcement in the bottom columns indeed can achieve a marked increase of the collapse-resistance capacities, and in the cases under consideration the increase of the CMRs are observed by an order of 25%.

ABSTRACT

In this study, an attempt has been made to assess the impact of proposed nonlinear conical spring bracing (NCSB) system on seismic response subjected to earthquake. The developed system includes of two telescopic conical spring springs that operate in axial compression. Due to shape of spring, the proposed system can performed as a nonlinear stiffness element that provide more lateral stability to structural frame. The action of NCSB does not control the low and moderate vibration due to earthquake but it acts for severe vibration whereas the frame displacement pass the allowable boundary. This inconstant performance avoids excessive effects of conventional bracing system if they attached as retrofitting components to moment resistant steel frame. by other words, due to the aforementioned characteristics of NCSB system, the inherent ductility of steel frame is not scarified and earthquake energy can be dissipate due to frame ductility, but, NCSB system provided more stability of structures and prevent large story drift. In this study, pushover and time history analyses has been conducted to evaluate the seismic performance of introduced device. The results from pushover disclose a considerable enhancement of structural capacity and ductility. Besides, the application on NCSB device changed the location of plastic hinge formation in structural elements. Furthermore, time history results proved the efficiency of NCSB device on reducing the maximum displacement.

Dynamic analysis, earthquake records, pushover analysis, nonlinear conical spring bracing, plastic hinge formation, ductility.

INTRODUCTION

Vibration impacts due to dynamic loads such as earthquake, wind and etc., can induce an unnecessary structure oscillations which may cause to catastrophic collapse. Improvement of structural performance subjected to dynamic loads is the most important concern in structural engineers, experts and researchers. The aforementioned enhancement shall consider the structural stability (safety) and economical design feasibility. It means that, the appropriate design technique especially choice of vibration control device is the most imperative issue to prevent the structure from any vibration induced failure. The prior earthquake design approach was based on inherent ductility of structures to dissipate the imposed earthquake energy. This practise was considered as the most feasible and safe design. But it may lead to unrealistic design and structural damage. A lot of research has been focused on supplementary energy dissipation devices which are installed in structures. Whereas these devices don't belong to main structural system can be offered as external energy dissipation system which can be easily substituted after severe excitation (Tsu T Soong and Dargush 1997). Vibration control techniques n can be categorized into three main types: active control (Yao 1972), passive control and semi active control. Passive control methods were introduced at the earliest stage, and were used commonly in seismic design procedure due to the minimum maintenance cost. Table 1, briefly presents the seismic control system which has been introduced in a few studies.

Active variable stiffness (AVS), a system for structural control has absorbed numerous attentions and interests. The desire effects and improvement of the structural performance in earthquake excitation of AVS systems were proven by previous studies(Takuji Kobori et al. 1993)(Yang, Wu, and Li 1996) Such a system has been investigated experimentally with implementation in full-scale building in Japan(T Kobori and Kamagata 1992). Most of available variable stiffness system are operated using external electrical controller which might cause delay in system performance. These systems are highly depended on energy recourse and also need repetitive maintenance. Variable stiffness bracing system is developed as retrofitting system for steel structures which included of four leaf springs in series with wire rope cable which its totally fabricate without dependency to electrical supply (Fateh et al. 2015)(Hejazi, Jaafar, and Fateh 2014).(Dct 2009) focused on the nonlinear behavior of the spring that could be achieved by varying the mean spring diameter in axial direction. In Conical

springs we have some advantages compared to cylindrical springs. In non-telescoping springs, the coils stack one above the other during compression. Another advantage of the conical springs can have a higher sideways stability, so they will better resist buckling. (Dct 2009).

The new bracing system with Nonlinear Conical Spring system was developed as adaptive structural control system to protect the building against severe vibration and ground movement. NCSB system includes nonlinear leaf springs which induce nonlinear and Nonlinear Conical Spring capacity at different frame displacement. The Nonlinear Conical Spring system (NCSB) system does not scarify the energy dissipation characteristics and ductility capability of moment resistance frame. For large vibration amplitudes, the bracing member and nonlinear spring acting and restrain unacceptably large storey drift. So, the braced frames can display ductile performance which is dissipating seismic energy.

DEVELOPMENT OF NCSB DEVICE

NCSB device installation in frame is shown in Figure 1. Once the frame subjected to dynamic force such as earthquake excitations, it sways to left and right and NCSB device intents to move to the right and left. Due to dual action of NCSB and compression resisting of conical spring, the induced force form vibration transfer to the device by cables. Since the cable is buckling free element, the force can be easily transfer to the main device in unlimited cycle. The action of NCSB can be divided to two main phases include solid telescopic conical spring and cable actions. For more explanation, whenever the device reaches to maximum deflection of conical spring, the cable stiffness adds to system stiffness since it works as braces which fixed at both ends.The 3D schematic model is presented in Figure 2.

The details of NCSB elements layout is describe in Figure 3. The NCSB device comprises of a nonlinear solid conical spring bracing attached to a cable to counter the dynamism of the force resulted from the vibration on the structure of a building The nonlinear conical spring bracing device further comprising, of a rectangular

frame having an exterior clamper (label 1) at each vertical side of the rectangular frame. A telescopic conical spring (label 2) attached at each end of the rectangular frame at the exterior clamper (lable1). Furthermore a steel rail (label 3) fixed at middle of the rectangular frame. An interior clamper (Label 4) attached to each telescopic conical spring (label 2), the cylindrical core (label 5) is slidable along the steel rail (label 3) and a steel rod (label 3) passes through each end of the rectangular frame and the interior clamper (4) and ended at the middle of the cylindrical core (label 5).

DYNAMIC EVALUATION OF NCSB IN DEVELOPED ARCS3D

The mathematical model of NCSB has been implemented in developed web based software called as ARCS3D which is abbreviated of Analysis of Reinforced Concrete Structure-3D. The push over and time history analysis of reinforced concrete (RC) structures furnished by NCSB device performed for 5-story building. More over the results compared with bare frame and efficiency of NCSB application has been discussed. The compressive concrete strength grade for both pushover and time history analyses are considered as 35 MPa. The columns and beams are modeled with same geometry sizes of 300 X 300 mm as shown in Figure 4. The diameter of reinforcement bars and concrete cover to steel bars are assumed 20 mm and 35 mm respectively in all the cases. In addition to, the story height and bay width for all models are 3 and 5 m correspondingly.

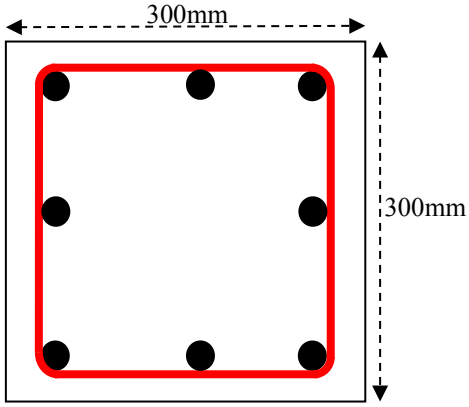

Figure 4 beams' and columns' sections

RESULTS AND DISCUSSIONS

Pushover Analysis

Pushover analysis is conducted for frame equipped with and without NCSB device as presented in Figure 5. The NCSB spring wire's diameter and spring's length are equaled to 8 and 120 mm respectively. The biggest and smallest diameters of conical spring considered as 400 and 150 mm. Furthermore, the diameter of wire rope cable equals to 10mm with high strength steel material. Results from pushover analysis for both models are reported in Figure 6. As can be observed, the implementation of NCSB device caused to increase the pushover capacity by 68 % and reached to 455 KN and also the ductility characteristic of frame furnished by NCSB enhanced. In addition to, the locations of plastic hinge formation in structures are monitored and presented in Figure 7. In the bare frame the plastic hinge initially formed at base nodes at columns then extended to upper columns. But, once the NCSB applied, the locations of plastic hinges altered and moved into the device around 61%.it means NCSB implementation in frame not only increase the structure capacity and ductility but also reduce the plastic hinge formation in structural components and shift them in NCSB device.

Time History Analysis

Time history analysis for bare and NCSB subjected to El-Centro North-South (1940) as shown in Figure 8, is conducted with developed finite element program. The 5-story models are analyzed with and without NCSB system. All beams are subjected to the equal 50Kn/m distributed loads. Moreover, 100KN point loads are applied at all columns as illustrated in Figure 9. The results reported in terms of time history of top node displacement. Figure 10 shows the displacement change verse time of considered top nodes in both models. As can be observed, application of NCSB device in frame caused to reduce the maximum absolute displacement about 35%.

CONCLUSION

This study introduced a rapid retrofitting technique for frame structures. Nonlinear conical bracing system comprised of two telescopic solid conical springs which are attached to wire rope cables. NCSB device can be applied as a new rapid retrofitting practice due to simplicity of NCSB fabrication and installation process in high ductility frame. Moreover it can be used as supplementary lateral resisting element in new framed building. Push over and time history analyses of 5–story RC frame with and without NCSB device has been performed. The results from push over analysis reveal the efficiency of NCSB device in structure. Not only the capacity and ductility characteristics of frame enhanced but also, the location of plastic hinge formations altered from main structural elements and shifted in NCSB device as supplementary energy dissipation system. Furthermore, time history analysis reports a considerable reduction of maximum displacement value.

For future study, finite element simulation is extremely essential to assess the NCSB ductility performance under monotonic displacement. Besides, the experimental dynamic test must be conducted to evaluate the seismic response of aforesaid method in reality by use of pseudo dynamic actuator or shaking table.

ACKNOWLEDGEMENT

This work received financial support from the Ministry of Science, Technology, and Innovation of Malaysia under Research Project No. 5524254. This support is gratefully acknowledged. The NCSB system is under filling patent grant at Malaysia intellectual property organizations (MyIPO).

ABSTRACT

Façades of office buildings conventionally consist of predominantly opaque walls or translucent glass panels. Due to recent economic and environmental concerns, innovative building façades, such as translucent concrete panels or double skin façades with green concrete, have started to be developed. These façade systems have considerable benefits in reducing energy consumption due to artificial electrical lighting and heating/cooling loads. However, initial costs associated with these emerging technologies are higher than their conventional counterparts. In this paper, a powerful decision making framework is used to evaluate the performance of innovative and conventional façades for a typical room of a representative building in Singapore, by taking into account lighting and thermal energy consumptions and initial cost. The adopted decision making framework is based on a recently extended version of multi-criteria decision analysis coupled with performance-based engineering methodology. The study shows that the performance of the innovative façade, despite its high initial cost, is comparable to glass façades.

INTRODUCTION

Façades of high-rise buildings conventionally consist of predominantly opaque walls or translucent glass panels. Due to recent economic and environmental concerns, innovative building façades, such as translucent concrete panels (TCPs) or double skin façades with green concrete, have started to be developed. While these façade systems have considerable benefits in reducing the energy expenditures and CO_2 emissions due to artificial lighting and heating/cooling systems, initial costs associated with these emerging technologies are higher than those of conventional façades. Therefore, a combined use of innovative façade systems and conventional onescan lead to an optimal solution in terms of a widespread range of indicators, namely cost, energy expenditure, CO_2 emission, and human comfort.

A preliminary investigation of the combined use of innovative and conventional façade systems is conducted in this study using a probabilistic decision framework, which is based on a recently extended version of multi-criteria decision analysis (MCDA) and performance-based engineering(PBE) (Mosalam et al. 2015). Three alternatives are considered by altering one of the walls for a typical room of a representative building in Singapore, while keeping the other three walls unchanged. These alternatives are defined by using: a) an opaque wall, b) a glass panel, and c) an innovative façade consisting of TCPs. Two of the unchanged walls are opaque with the third wall having a window opening. Probability of exceedance (POE) and expected value of the utilities are computed for the three alternatives considering the light and thermal energy consumptions and the initial cost as the indicators.

METHODOLOGY: PBE-MCDA

MCDA is considered as an essential tool to select the best solution amongst various alternatives. There are many MCDA methods applied to many problems. In general, they are classified into three categories(Wang et al. 2009):

1) Elementary, e.g. weighted sum method (WSM) and weighted product method (WPM);

2) Outranking, e.g. elimination of choice translating reality (ELECTRE) method and preference ranking organization method for enrichment evaluation (PROMETHEE);

3) Unique synthesizing criteria, e.g. analytic hierarchy process (AHP), technique for order of preference by similarity to ideal solution (TOPSIS), simple multi-attribute rating technique (SMART), MCDA combined fuzzy method, and multi-attribute utility/value theory (MAUT/MAVT).

There are other methods which are not included in the above categories, e.g.novel approach to imprecise assessment and decision environments (NAIADE), measuring attractiveness by a categorical-based evaluation technique (MACBETH), and preference assessment by imprecise ratio statements (PAIRS). Among the MCDA methods mentioned above, AHP, SMART, and MAUT/MAVT are closely related. In particular, SMART and MAUT/MAVT are widely used in the utility or value function-based assessment. The main difference between them is the linearity of the utility/value functions, which is required in SMART. Some MCDA methods derived from the ones mentioned above address the environmental aspects of a building design, e.g.integrated value model for sustainable assessment (MIVES)(Lombera and Aprea 2010; Pons and Aguado 2012). They deal with conflicts arising among environmental indicators (Gustavsson and Sathre 2006). In this study, a version of MAUT, recently enhanced to take into account uncertainties of indicators, is used for investigation of different façade configurations.

The MAUT, developed by Keeney and Raiffa(1993), provides an analytical framework to deal with decision problems that involve multiple criteria (Mosalam et al. 2015). In this framework, each alternative receives a single-attribute value function for each indicator, and these scores are combined into an overall value by the assignment of weights to each indicator. Table 1 lists considered indicators and corresponding weights in this investigation.

Table 1. Indicators and corresponding weights for the considered room.

Indicator	w_{ind}
Light energy consumption (LE)	0.2
Thermal energy consumption (TE)	0.3
Initial cost (IC)	0.5

The objective of the MAUT is to determine the most sustainable design alternative out of the three considered ones using the indicators listed in Table 1. Eq. 1 constitutes the simplest form to be used by the MAUT for this decision. The utility functions, u_{LE}, u_{TE}, and u_{IC}transform the response of each indicator into a normalized value (between 0 and 1) to allow consideration of heterogeneous indicators with different units. The corresponding weights, w_{LE},w_{TE}, andw_{IC}, are assigned to these utility functions where their sum is 1.0. Accordingly, the combined utility function, $U(a,b,c)$, can be interpreted as the weighted average of the utility functions of the individual indicators.

$$U(a,b,c) = w_{LE}u_{LE}(a) + w_{TE}u_{TE}(b) + w_{IC}u_{IC}(c) \tag{1}$$

Eq. 1 is mainly valid for deterministic indicators. However, considered indicators possess inherent uncertainties. The uncertainty in light and thermal energy consumptions are attributed to that in the outside weather conditions, while the variability of the market prices causes the initial cost uncertainty. Accordingly, considered indicators are not defined by deterministic values, rather each particular value of each indicator has a certain probability of occurrence defined by a distribution given in terms of a probability density function (PDF), f, as shown in Eq.2. For mutually independent indicators, as the case in this investigation, $f(LE,HE,IC)$is simply calculated by Eq. 3.

$$f(LE,TE,IC) = f(LE)\times f(TE\,|\,LE)\times f(IC\,|\,TE,LE) \tag{2}$$

$$f(LE,TE,IC) = f(LE)\times f(TE)\times f(IC) \tag{3}$$

Incorporation of Eq. 2 orEq. 3 and the consequent involvement of uncertainty quantification and probabilistic computations transform the classical MAUT methodology to the PBE domain, where the resulting decision making tool is designated as PBE-MAUT in the remainder of this paper. Developing the PDFs in PBE-MAUT gives the decision maker the opportunity to stochastically evaluate the considered alternatives. A decision maker

can determine a central utility metric by calculating expected value of utility for each alternative, Eq. 4. Analogues to Eq. 1, Eq. 4 represents a weighted average of each possible value of the combined utility, where the weights are defined by the corresponding probabilities.Moreover, by calculating the POE values, the decision makercan take decisions according to his/her risk preference. In this study, two POE-related metrics are defined: 1) U_{f50}determined as the utility value with POE of 0.5 and 2) U_{f90} determined as the utility value with POE of 0.9. U_{f50} and U_{f90}represent metrics that would be likely used by decision makers who are risk-neutral and risk-averse, respectively. Figure 1 outlines the application of PBE-MAUT for the investigation of the combined use of innovative and conventional façade systems in this study.

$$E(U)=\int_{LE_1}^{LE_2}\int_{TE_1}^{TE_2}\int_{IC_1}^{IC_2}U(LE,TE,IC)\,f(LE,TE,IC)\,dLE\,dTE\,dIC \tag{4}$$

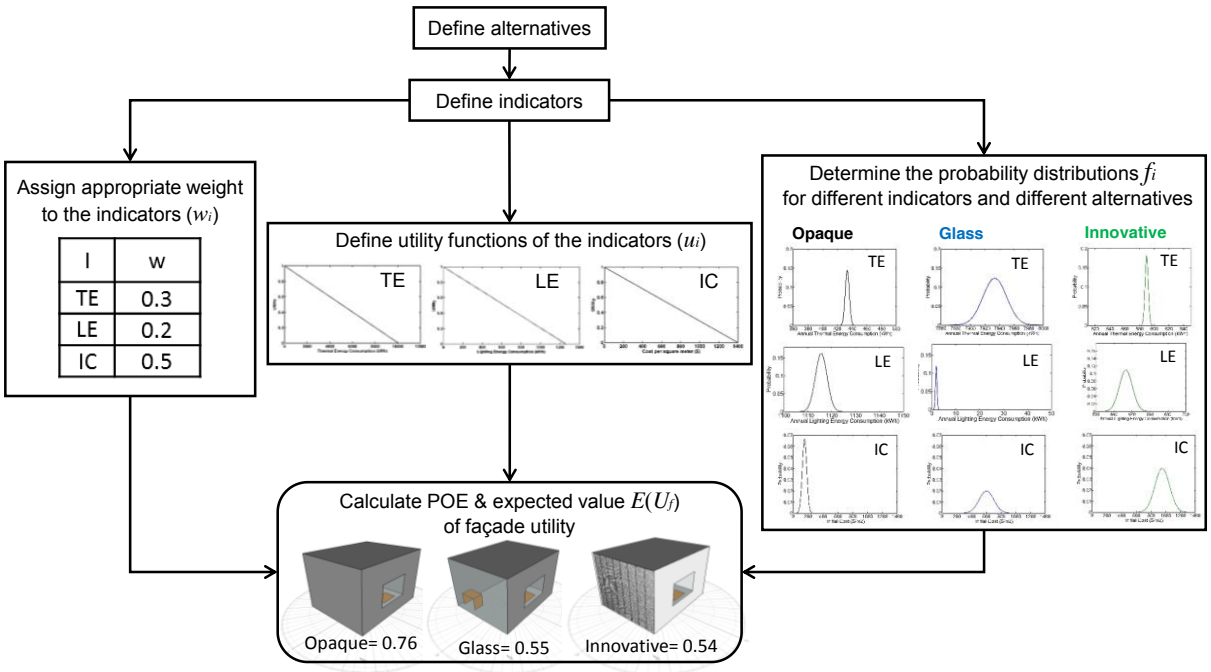

Figure 1. Outline of the application of PBE-MAUT for the investigation of different façade systems.

CASE STUDY

Setup

A case study is designed to evaluate the performance of different façade systems using the decision making tool PBE-MAUT. In this problem, the decision maker needs to decide between using conventional facades like opaque and glass façades or choosing an innovative façade. Thus, the decision space consists of three façade alternatives: Opaque, Glass, or Innovative. For this investigation, a one room (4.5m × 3.65m) office space in Singapore, with all opaque walls except a south-facing window, is modeled. The room has two desk spaces: one near the window (A) and the other at the farthest corner (B) of the window, Figure 2. Considered alternatives in the study and shown in Figure 3are defined by setting the west facing façade (Area A_f= 11.14m^2)as concrete block wall (Opaque), double glazed glass (Glass),or TCPs (Innovative).

For the opaque façade, a concrete block wall is considered with plasters on both sides (thickness d=150mm and thermal conductivity k= 0.8 W/m-K). For the translucent façade, a double pane glass façade (solar heat gain coefficient, *SHGC*=0.8 and visible transmittance, *VT*= 0.7) has been considered. TCPs represent an innovative façade system with optical fibers inserted in concrete panels to transmit daylight (Ahuja et al. 2014) and consequently reduces the usage of artificial lighting systems. Recently, the light energy savings objective of TCPs has been combined with a thermal energy savings objective, by employing ultra-light weight cement composites (ULCC) as the concrete mix. ULCC has significantly low thermal conductivity, k=0.43W/m-K, compared to conventional concrete, k=1.98 W/m-K (Wu et al. 2015).The TCPs, produced recently at UC Berkeley with ULCC, are considered as the innovative façade alternative with thickness d = 50 mm.

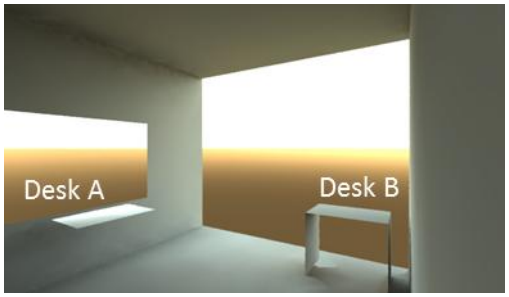

Figure 2. The desk spaces in the studied room.

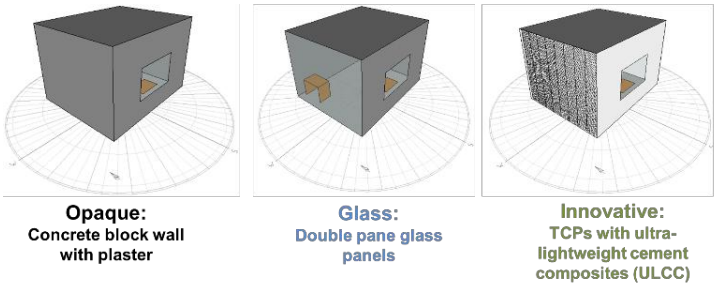

Figure 3. Opaque, Glass, and Innovative façades as the three alternatives of the decision problem.

Probability Distribution of the indicators

An ideal way to develop the probability distribution of the indicators would be to obtain thermal and lighting consumption data experimentally for multiple years. Since such data are not available, simulation tools currently used in design processes are employed herein.

Thermal Energy Consumption

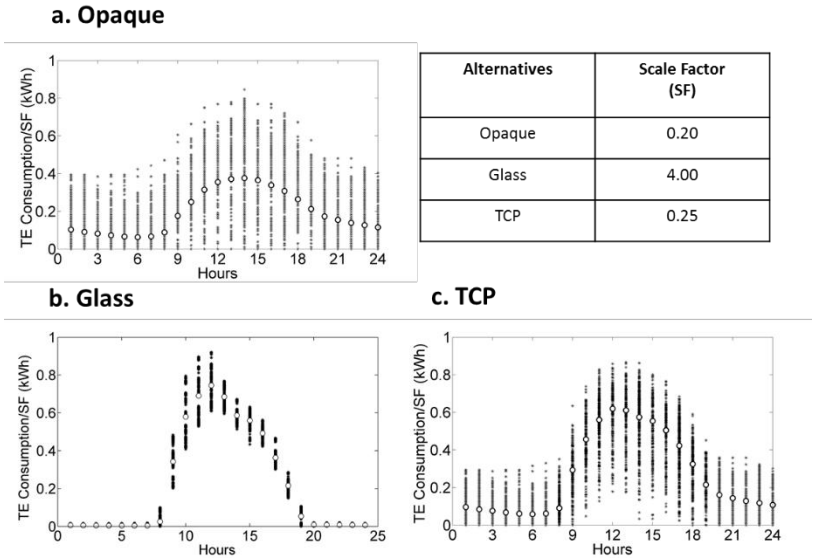
In order to determine the PDF for annual thermal energy (*TE*) consumption, *f* (*TE*), selected material properties are used. Outside dry bulb temperature, T_{out}, and hourly incident solar radiation, *IR*, are determined from the weather file of Singapore Airport Weather station. Using such data, hourly cooling load *Et* for a year is calculated from Eq. 5 as the sum of conductive, convective, and radiative energy contributions, assuming an indoor temperature, T_{in}= 25°C, corresponding to comfortable indoor conditions in Singapore. While calculating this energy exchange, it was assumed that internal gains and infiltration losses are same for all three alternatives and therefore are not included.

$$Et = (k/d + h) \times A_f \times (T_{out} - T_{in}) + U_w \times A_w \times (T_{out} - T_{in}) + SHGC \times IR \times A_w \quad (5)$$

where *h* is the air film conductance, U_w is taken as 2.82 W/m^2-K for the *U*-value of the glass window and is taken as 2.92 W/m^2-K for the *U*-value of the optical fibers in the TCPs (about 2.57% of the surface area represent the optical fiber density), and A_w is the window area with window to walls ratio (WWR) of 0.043 and 0.270 for the opaque and glass alternatives, respectively.

Hourly *TE* consumption is plotted in Figure 4for the 365 days of a representative year for the three alternatives, together with mean values from 365 days indicated with large open circles. Figure 4 shows that, as the temperature gradually rises during the midday, thermal energy consumption also rises for all three alternatives. For opaque and innovative façades, this rise reaches 0.17and 0.23kWh, respectively, whereas for the glass façade, *TE* consumption peaks at 3.8kWh indicating that glass façade would be the least suitable alternative if only *TE* consumption was considered in the decision making. The mean and standard deviation of *TE* are calculated for each hour from the 365 days data. By using these mean and standard deviation values for the hourly *TE* consumption, Monte Carlo simulation is performed to extend the data to obtain the *TE* for all days of 30 years (total of 365 × 30 × 24*TE* values), where30 years represents the design life of the typical buildings in Singapore. Summing the 365 × 24values, annual *TE* consumption is determined for the 30 years. Probability distribution for *TE* consumption, *f*(*TE*),is assumed as a normal distribution with parameters obtained as the mean and standard

deviation of the 30 annual *TE* values for all three alternatives. Flowchart of the devised algorithm and the resulting probability distributions are shown in Figures 5 and 8, respectively.



Alternatives	Scale Factor (SF)
Opaque	0.20
Glass	4.00
TCP	0.25

Figure 4. Hourly *TE* consumption for a representative year for all alternatives (Table reports the multiplier of the *TE* consumption on the vertical axis for the different alternatives).

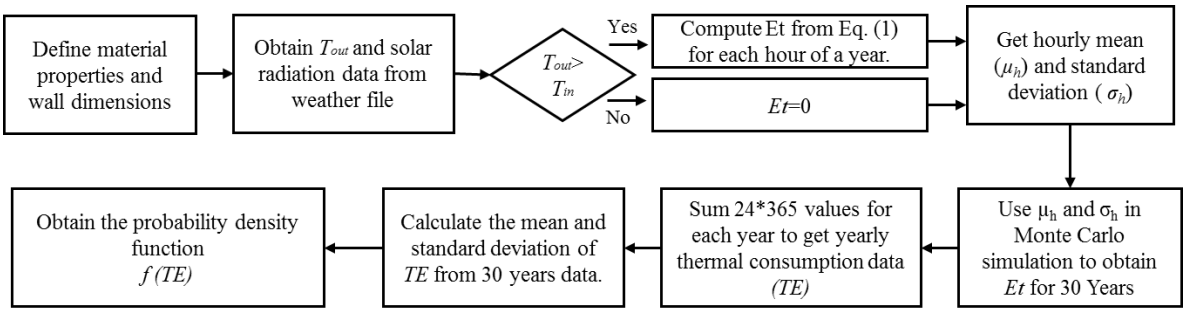


Figure 5. Algorithm devised to obtain the PDF for the annual *TE* consumption.

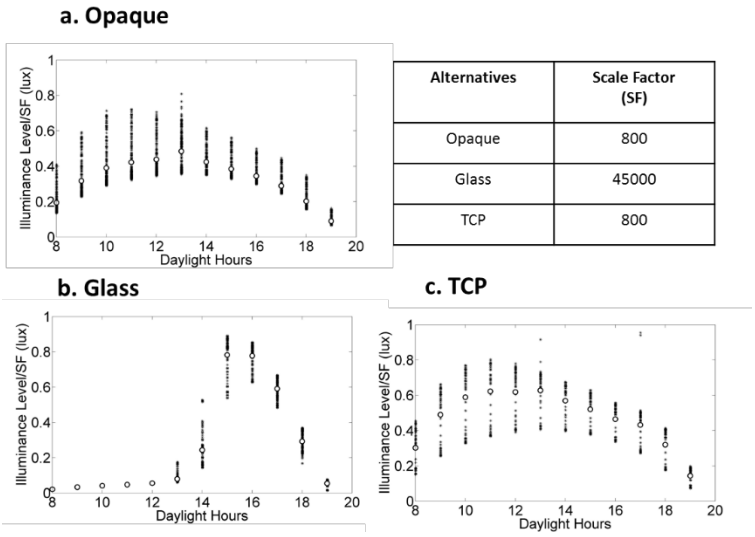
Light Energy Consumption

For determination of the light energy (*LE*) consumption PDF, *f*(*LE*), the room is modeled in *Ecotect* (2011) with respective visual transmittance properties and illuminance value is calculated at both desks by exporting the model to *RADIANCE*(2014)and using the daylight data obtained from the weather file. In an office, the minimum amount of light on the working plane enforced by the building code (Section 9, ASRAE Standard 90.1.2007) is 400 Lux. It is assumed that the lights (three sets of three T8 tubes) are on if light level is below this recommended 400 Lux in any of the two working desks. Figure 6shows that mean hourly illuminance level at desk B does not exceed the 400 Lux level for opaque façade but frequently exceeds that for the innovative façade and always exceeds that for the glass façade. Accordingly, glass façade outperforms the opaque and innovative façades when *LE* is considered. From hourly mean and standard deviation values, annual *LE* consumption for 30 years have been calculated and *f*(*LE*) distributions have been developed in similar manner to the *f*(*TE*) as shown in Figure 8. Figure 7 presents the algorithm devised to calculate the PDF of the *LE* consumption.

Initial Cost

Data for cost which include material and labor costs have been obtained from market survey in the US. Material and labor cost for the opaque façade is the least ($150/m^2). Use of optical fiber and unconventional manufacturing process make the innovative façade the most expensive alternative among the three ($950/m^2). However, installation cost for double glazed façade ranges from $200 to $300/m^2 making this double glazed façade a moderately expensive alternative. Although, price of constructing the investigated façades may be different in

Singapore compared to US, it is assumed that the ratio of the mean cost will be almost the same in both countries. Figure 8 shows the assumed distributions of the initial cost $f(IC)$ for all three alternatives.



Alternatives	Scale Factor (SF)
Opaque	800
Glass	45000
TCP	800

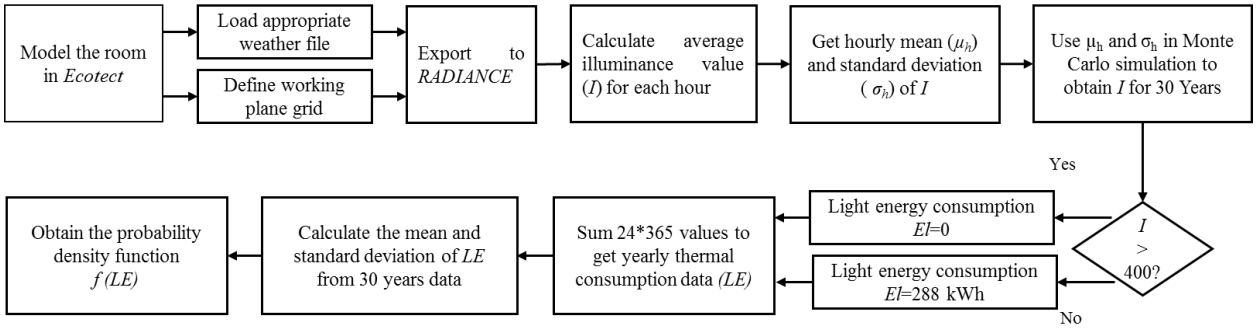

Figure 7. Algorithm devised to obtain the PDF for annual *LE* consumption.

Utility Functions

In a decision problem like the one presented here, most often, different attributes will yield best consequences. Hence, an objective function is required to rank the consequences taking into account risk preference of the decision maker (Keeney 1982). In decision analysis, these objective functions are referred to as utility functions $u(x)$. These utility functions also transform values of each indicator to a normalized value between 0 and 1 in order to consider response of indicators with different units, i.e. heterogeneous indicators.

In this study, risk neutral (linear) utility functions, defined by Eq. 6 and plotted in Figure 9, are used for the indicators. For *LE* consumption, the case when lights are never and always on have utility values of 1 and 0, which correspond to the annual *LE* consumptions of LE_a = 0 and LE_b = 1,261 kWh, respectively. For *TE* consumption, the case when no artificial energy is required to maintain comfortable indoor condition has a utility of 1 and the case where there is no façade to stop heat from escaping outside has utility of 0. These two cases correspond to the annual *TE* consumptions of TE_a = 0 and TE_b = 10,000 kWh, respectively. For cost, utility of 1 indicates no cost associated with façade construction (i.e. IC_a = 0) and utility of 0 refers to the maximum amount the decision maker can possibly spend on a façade, assumed to be IC_b = \$1400/m^2 in this study.

$$u(x)=\begin{cases}1 & x \le x_a \\ 1-\dfrac{x-x_a}{x_b-x_a} & x_a \le x \le x_b \\ 0 & x \ge x_b\end{cases} \tag{6}$$

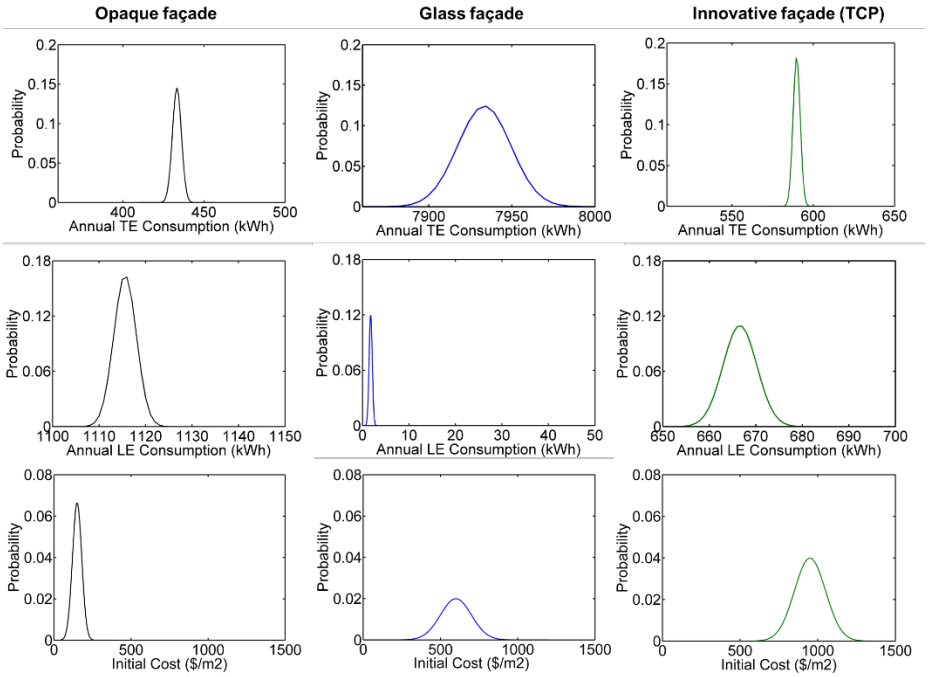

Figure 8. PDFs for three indicators of all three alternatives.

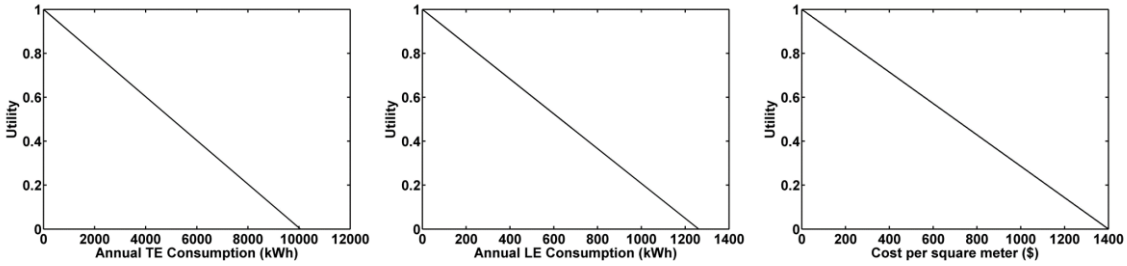

Figure 9. Utility functions of the three alternatives.

Weight of the Indicators

Weights of the indicators depend on the preferences and priorities of a decision maker. If there are multiple decision makers, the weights will be decided according to their mutual agreement. In this study, weights are approximated by referring to the preferences in similar projects and energy use data. Initial cost has always been the primary decisive factor in many construction projects. For this reason, *IC* corresponds to 50% weight of this decision problem (w_{IC}=0.5). Energy consumption breakdown of commercial buildings show that heating and cooling load include about 30% to 35% of the total energy consumption whereas lighting load is about 20%(DOE 2012). Accordingly, w_{TE} and w_{LE} are considered to be 0.3 and 0.2, respectively.

RESULTS AND DISCUSSION

After developing the PDFs, defining utility functions and assigning appropriate weights for each indicator, different metrics, listed in Table 2, can be used to evaluate the performance of each façade alternative. This study shows that, in Singapore, opaque façade has the highest probability of being the "Best" alternative. From Figure 10, it is also observed that the opaque façade stochastically dominates the glass and innovative façades. Thus, a risk neutral or a risk averse decision maker will most likely choose the opaque façade over the innovative one.

Innovative façade can achieve 92% annual *TE* consumption reduction when compared to the glass façade. On the other hand, it can reduce *LE* consumption by 40% compared to an opaque façade. This energy savings are negated by its high *IC* when compared to an opaque façade which has almost 10 times lower *IC*. However, innovative façade is performing comparably to glass façade despite its higher *IC*. This indicates that some design modification of the innovative façade to enhance its energy savings or adapting to a more cost efficient manufacturing process will make it a superior candidate to glass and possibly opaque façades.

Table 2.Utility values to evaluate the performance of each alternative by PBE-MAUT.

Alternative	E(U_f)	U_{f50}	U_{f90}
Opaque	0.76	0.76	0.74
Glass	0.55	0.55	0.50
Innovative	0.54	0.54	0.49

CONCLUDING REMARKS AND FUTURE EXTENSIONS

The goal of performance-based engineering is to provide a design that will deliver best performance using an approach that considers various design aspects and the priorities of various stakeholders in a holistic manner. The decision tool PBE-MAUT presented hereinallows the decision makers to consider the whole life cycle and all components of a building together with the associated uncertainties.

In this paper, PBE-MAUT methodology was applied to investigate the performance of different façade systems. This study presented a scenario where each alternative is superior to others in one aspect. As a result, choosing the "Best" alternative was not straightforward for a decision maker. The PBE-MAUT decision making framework provided the decision maker a robust quantitative tool to consider multiple attributes with different measuring units while making the decision. Results of the study showed that the opaque façade is suited for office spaces in Singapore if energy consumption and initial cost is considered. The result could be different if several other indicators such as maintenance cost, constructions safety, and human comfort were considered or if the current indicators were employed with different weights.

This decision tool PBE-MAUT can also be utilized as an important design tool. In this study, innovative façade is the least preferred choice but changing façade parameters, reducing cost, or a combination of these two issues is likely to improve its performance. However, this study is conducted for a typical office room in Singapore. The conclusions inferred from this study are likely to change when a study is conducted for the building scale with more indicators. Moreover, the assumption of the ratio of initial cost of the different alternatives being the same in Singapore and the US may not hold due to lack of availability of raw materials in Singapore. Future research will be conducted by taking into account more representative cost information and considering other important indicators on a building scale.

ABSTRACT

Compared to traditional Reliability Index Approach (RIA), Performance Measure Approach (PMA) is considered to be more efficient and stable for evaluation of probabilistic constraints in reliability-based design optimization of structures. In PMA, the probabilistic performance measure is obtained through locating the minimum performance target point (MPTP) with the specified target reliability index in standard normal space. The advanced mean-value (AMV) method is well suitable for locating MPTP due to its simplicity and efficiency. However, the iterative sequence may converge very slowly, or oscillate and fail to converge if the performance function is highly nonlinear. Several modified algorithms were suggested to enhance the convergence of AMV, but their implementation is complicated and the prior knowledge of convexity or concavity of the performance function is needed. In this paper an easy iterative algorithm, which introduces a "new" step size to control the convergence of the sequence, is proposed. This step size is new because it may be constant during the iteration or decreases successively using a self-adjust strategy. It is proved that the AMV method is a special case of this proposed algorithm when the step size tends to infinity. Numerical results of several nonlinear performance functions indicate that the proposed algorithm is effective and as simple as the AMV but more robust.

INTRODUCTION

Uncertainties are observed in material and geometric properties and external loads during structures' lifetime. Consequently, the reliability-based design optimization (RBDO) is indispensable and rational (Tu et al 1999; Yang and Gu 2004; Chiralaksanakul and Mahadevan 2005; Cheng et al, 2006; Zou and Mahadevan 2006). The RBDO formulation is usually expressed as the minimization of objective function under probabilistic constraints and the effectiveness, robustness and efficiency of the assessment of probabilistic constraints are the key of smooth implementation for RBDO. There are two approaches to evaluate probabilistic constraints: reliability index approach (RIA) and performance measure approach (PMA) (Tu et al 1999). The latter is also referred to as inverse reliability analysis (Kiureghian et al 1994; Li and Foschi 1998).

In RIA, the sub-problem of constraint evaluation is transformed to check if the reliability index β is greater than the specified target reliability index and β is the distance between the origin and the most probable failure point (MPFP) on the limit state surface in the standard normal random variable space. Whereas, in PMA the constraint evaluation is to check if the probabilistic performance measure (PPM) G_p is greater than zero and G_p is the performance function value at the minimum performance target point (MPTP) with the specified target reliability index in the standard normal space. Compared with RIA, it is thought that PMA has higher efficiency and superior numerical stability (Tu et al 1999; Lee et al 2002; Youn et al 2003; Du et al 2004; Lee and Lee 2005; Yi et al 2008). The iterative scheme of advanced mean value (AMV) is well suitable for PMA due to the simplicity and efficiency. However, for some nonlinear performance functions the iterative sequences of AMV formulation could yield non-convergence solutions such as the periodic oscillation observed in the references (Lee et al 2002; Youn et al 2003; Youn and Choi 2004; Du et al 2004). Hence, several improved algorithms aiming to enhance the convergence of AMV were suggested. Youn and his research team proposed conjugate mean value method (CMV) (Youn et al 2003), hybrid mean value method (HMV) (Youn and Choi 2004), and enhanced hybrid mean value method (EHMV) (Youn et al 2005a). However, these algorithms need the prior knowledge including normal vectors of several iterative points and convexity or concavity of the performance function, and require complicated implementation (Youn et al 2005a; Youn et al 2005b). Furthermore, they could still fail to converge for some problems. Yang & Yi (2009) employed the stability transformation method of chaos control (CC) to achieve the oscillation, bifurcation and chaos control for the solution of the AMV iterative procedure. Although the CC method performs well for nonlinear performance functions, it is computationally inefficient. Accordingly Meng et al (2015) proposed a modified chaos control (MCC) method, which improved the convergence by extending the iterative point of the CC method to the constraint boundary. But for both CC and MCC method, it is not easy to select the appropriate factor and involutory matrix, especially for high-dimensional random space.

In this paper, an easy iterative algorithm, which introduces a "new" step size to control the convergence of the sequence, is proposed. This step size is new because it may be constant during the iteration or decreases successively using a self-adjust strategy. It is proved that the AMV method is a special case of this proposed algorithm when the step size tends to infinity. Numerical results of several nonlinear performance functions, including an engineering application, indicate that the proposed algorithm is effective and as simple as the AMV but more robust.

PROPOSED ITERATION ALGORITHM

Basic iteration formulation

To measure probabilistic performance using inverse reliability analysis, one first needs to transform the original random vector $\mathbf{x}$ to a standard Gaussian vector $\mathbf{u}$ (zero means, unit variance and independent components), expressed as $\mathbf{u} = \mathrm{T}(\mathbf{x})$ or $\mathbf{x} = \mathrm{T}^{-1}(\mathbf{u})$. Then the performance function $G(\mathbf{d},\mathbf{x}) = G(\mathbf{d},\mathrm{T}^{-1}(\mathbf{u})) = g(\mathbf{d},\mathbf{u})$, in which $\mathbf{d}$ is the design variable vector, representing either deterministic physical quantities or parameters of the probability distribution of the random variables (e.g. the mean values or standard deviations of the random variables). The performance function $G(\mathbf{d},\mathbf{x}) < 0$ denotes

the failure domain. The probabilistic performance measure $G_p(\mathbf{d})$ can be obtained from an optimization problem in standard normal **u**-space (Tu et al 1999; Lee et al 2002),

$$\begin{aligned} &\text{for any given } \mathbf{d} \quad \text{find } \mathbf{u}^*, \text{ such that} \\ &\text{minimize} \quad g(\mathbf{d},\mathbf{u}) \\ &\text{s.t.} \quad \|\mathbf{u}\| = \beta_t \end{aligned} \tag{1}$$

where $\mathbf{u}^*$ is the minimum performance target point (MPTP) on the sphere surface with the target reliability index β_t and PPM $G_p(\mathbf{d}) = g(\mathbf{d},\mathbf{u}^*) = G(\mathbf{d},\mathbf{x}^*)$. Hereafter **d** will be omitted for concision.

In PMA, AMV algorithm, which can be derived from the KKT conditions of the optimization formulation (1), is commonly used because of its simplicity and efficiency. The iterative formula of AMV is expressed as Eq. (2) and Figure 1 shows the iterative procedure of AMV method.

$$\mathbf{u}^{k+1} = \beta_t \mathbf{n}(\mathbf{u}^k) \qquad \mathbf{n}(\mathbf{u}_k) = -\frac{\nabla_{\mathbf{U}} g(\mathbf{u}^k)}{\|\nabla_{\mathbf{U}} g(\mathbf{u}^k)\|} \tag{2}$$

where $\mathbf{u}^k = (u_1^k, u_2^k, \cdots, u_n^k)$ is the *k*-th iteration point on the target reliability surface. $\nabla_{\mathbf{U}} g(\mathbf{u}^k) = (\frac{\partial g}{\partial u_1^k}, \frac{\partial g}{\partial u_2^k}, \cdots, \frac{\partial g}{\partial u_n^k})$ is the gradient vector of performance function at point $\mathbf{u}^k$. $\mathbf{n}(\mathbf{u}^k)$ is the negative gradient direction at point $\mathbf{u}^k$, as shown in Figure 1.

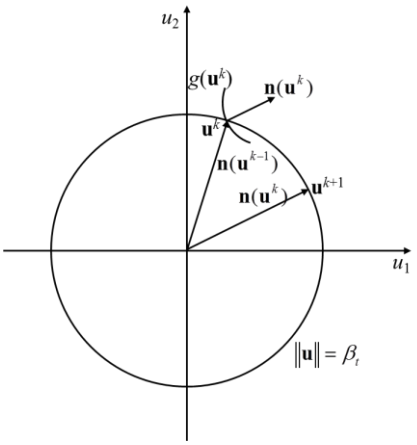

Figure 1 Iterative procedure of AMV method

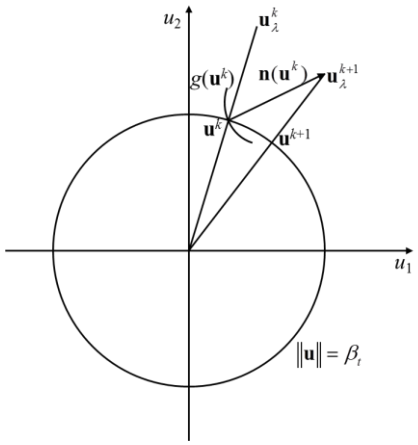

Figure 2 Iterative procedure of the proposed method

It is found that if the limit surface is flat, AMV method converges fast. However, for some nonlinear performance functions the iterative sequence of AMV could yield non-convergence solution such as the periodic oscillation observed in the references (Lee et al 2002; Youn et al 2003; Youn and Choi 2004; Du et al 2004). Here a "new" step size parameter to control the convergence of the sequence is proposed.

As shown in Figure 2, $\mathbf{u}^k$ and $\mathbf{n}(\mathbf{u}_k)$ have the same meanings as that in Figure 1. We can get a point

$\mathbf{u}_\lambda^{k+1}$ by moving a step with size λ (>0) along the negative gradient direction from point $\mathbf{u}^k$. The k+1-th iteration point, $\mathbf{u}^{k+1}$, is the intersection point of the target reliability sphere surface and the line, which connects the point $\mathbf{u}_\lambda^{k+1}$ to the origin. The expressions are as follows:

$$\mathbf{u}_\lambda^{k+1} = \mathbf{u}^k - \lambda \nabla_{\mathbf{U}} g(\mathbf{u}^k) \qquad \mathbf{u}^{k+1} = \beta_t \frac{\mathbf{u}_\lambda^{k+1}}{\left\| \mathbf{u}_\lambda^{k+1} \right\|} \tag{3}$$

It can be seen in Figure 2 that $\mathbf{u}_\lambda^{k+1} = \mathbf{u}^k$ if $\lambda = 0$, which means the iteration points are in fixed position and the iteration procedure will never converge to the MPTP. So we must set $\lambda > 0$. If $\lambda \to \infty$,

$$\begin{aligned} \lim_{\lambda\to\infty} u_i^{k+1} &= \lim_{\lambda\to\infty} \beta_t \frac{u_i^k - \lambda \dfrac{\partial g(\mathbf{u}^k)}{\partial u_i}}{\sqrt{\sum_{i=1}^{n} (u_i^k - \lambda \dfrac{\partial g(\mathbf{u}^k)}{\partial u_i})^2}} = \lim_{\lambda\to\infty} \beta_t \frac{u_i^k / \lambda - \dfrac{\partial g(\mathbf{u}^k)}{\partial u_i}}{\sqrt{\sum_{i=1}^{n} (u_i^k / \lambda - \dfrac{\partial g(\mathbf{u}^k)}{\partial u_i})^2}} \\ &= -\beta_t \frac{\dfrac{\partial g(\mathbf{u}^k)}{\partial u_i}}{\sqrt{\sum_{i=1}^{n} [\dfrac{\partial g(\mathbf{u}^k)}{\partial u_i}]^2}} \qquad (i = 1, 2, \cdots, n) \end{aligned} \tag{4}$$

This is just the iteration formulation of the AMV method shown in Eq. (2). It means the AMV method is a special case of this proposed algorithm when the step size tends to infinity.

Determination of the Step Size

When $\left\| \mathbf{u}^{k+1} - \mathbf{u}^k \right\| > 0$, one can always find a proper value of λ, which makes $\left\| \mathbf{u}^{k+1} - \mathbf{u}^k \right\| > \left\| \mathbf{u}^{k+2} - \mathbf{u}^{k+1} \right\|$. Suppose $\left\| \mathbf{u}^{k+2} - \mathbf{u}^{k+1} \right\| = t^{k+1} \left\| \mathbf{u}^{k+1} - \mathbf{u}^k \right\|$, where $0 < t^{k+1} < 1$. There must be a sequence of λ which makes

$$\begin{aligned} &\lim_{k\to\infty} \left\| \mathbf{u}^{k+2} - \mathbf{u}^{k+1} \right\| = \lim_{k\to\infty} t^{k+1} \left\| \mathbf{u}^{k+1} - \mathbf{u}^k \right\| = \lim_{k\to\infty} t^{k+1} t^k \left\| \mathbf{u}^k - \mathbf{u}^{k-1} \right\| \\ &= \lim_{k\to\infty} t^{k+1} t^k t^{k-1} \left\| \mathbf{u}^{k-1} - \mathbf{u}^{k-2} \right\| = \cdots = \lim_{k\to\infty} t^{k+1} t^k t^{k-1} \cdots t^2 \left\| \mathbf{u}^2 - \mathbf{u}^1 \right\| = 0 \end{aligned} \tag{5}$$

Eq. (5) means the proposed method can always converge when setting a appropriate value of λ.

Then how to set a appropriate value for step size λ to guarantee convergence of the iteration process? The appropriate value for λ depends on the order of nonlinearity of the performance function in standard normal space. λ should be small if the order of nonlinearity of the performance function is high. Computational results of the following examples show that performance functions with different nonlinear degree have relevant maximum values $\lambda_{\max}$ and the iterative sequence can converge only when $0 < \lambda < \lambda_{\max}$. When the nonlinear degree is relatively low, $\lambda_{\max} = \infty$ and the AMV method, the special case of the proposed algorithm,

can be used. However the performance function's nonlinear degree is usually unpredictable and even if it can be predictable, the quantity relation between $\lambda_{\max}$ and the nonlinear degree is impossible to constitute. Consequently we must "try" in practical application and this troublesome trying work can be done by computers. Firstly, a relatively large value is set for λ. If $\left\|\mathbf{u}^{k+2}-\mathbf{u}^{k+1}\right\|>\left\|\mathbf{u}^{k+1}-\mathbf{u}^{k}\right\|$ for a certain iteration in the iterative process, set $\lambda=\lambda/c$. Here *c*, named adjusting coefficient for step size, is a constant greater than 1. Computational examples indicate good results can be obtained when *c* is set between 2.2~2.6. Of course there is no need to adjust λ if the initial value of λ is less than $\lambda_{\max}$. In addition, the smaller the step size is, the more iterations are needed. This proposed method can be named as step-size-adjustment iterative algorithm.

Iterative Process

The proposed algorithm consists of the following steps.
Step 1: Transform the original random variable vector **x** into a standard normal vector **u**.
Step 2: Set k=0 and determine initial iterative point $\mathbf{u}^0$ (we usually set $\mathbf{u}^0$=0), initial step size λ and adjustment factor for step size *c*. Generally, we set $0<\lambda<10$ and 2.2<*c*<2.6. ε is convergence precision.

Step 3: Calculate the gradient vector of performance function $\nabla_{\mathbf{U}}g(\mathbf{u}^k)$ at point $\mathbf{u}^k$ according to finite difference method.
Step 4: Calculate $\mathbf{u}^{k+1}$ from Eq. (3)

Step 5: If $\left\|\mathbf{u}^{k+1}-\mathbf{u}^{k}\right\|<\varepsilon$, stop the iteration and $\mathbf{u}^{k+1}$ is MPTP. Otherwise, go to step 6.

Step 6: If $\left\|\mathbf{u}^{k+1}-\mathbf{u}^{k}\right\|>\left\|\mathbf{u}^{k+2}-\mathbf{u}^{k+1}\right\|$, return to step 3. Otherwise, decrease the step size using $\lambda=\lambda/c$, and then return to step 3.

ILLUSTRATIVE EXAMPLES

In this section, several examples including an engineering application with different nonlinear degree of the performance functions are given to demonstrate the effectiveness, robustness and efficiency of the proposed method.

Example 1 A performance function is given as (Youn et al (2003)) :

$$G=-\exp(x_1-7)-x_2+10$$

This problem contains two independent random variables $\mathbf{x}=[x_1\ x_2]$ with normal distribution $x_i\sim N(6.0,0.8)$, i=1,2. The target reliability index is $\beta_t=3.0$.

Table 1 shows the results of PPMs and corresponding iterations using the proposed method with different λ and using the AMV algorithm. The AMV algorithm can converge because the nonlinear degree of the performance function is relatively low. In other words, $\lambda_{\max}=\infty$ for this problem. From Table 1, we can see that all the resulting PPMs are the same, but the iterations are different when using the proposed method with

different λ. The larger the value of λ is, the less iterations are needed to converge. The number of iterations is the same with that of the AMV algorithm when λ is greater than 10 and the proposed method retrogresses to the AMV method.

Table 1 Results of PPM and iterations for different λ

λ	0.05	0.1	0.5	1	5	10	>10	AMV	CMV(Youn et al (2003))
Iterations	145	80	23	15	8	8	7	7	12
G_p	-0.354	-0.356	-0.358	-0.358	-0.358	-0.358	-0.358	-0.358	-0.358

Example 2 Consider the following performance function(Meng et al (2015)):

$$G(\mathbf{x}) = 0.3x_1^2x_2 - x_2 + 0.8x_1 + 1$$

$$x_1 \sim N(1.2, 0.42) \quad x_2 \sim N(1.0, 0.42) \quad \beta_t = 6.0$$

The iterative results of different approaches are listed in Table 2. It is seen that the AMV algorithm fails to converge while all the other methods can converge. However, the proposed method converges to MPTP accurately after only five iterations and it is much more efficient than other algorithms. **Figure 3** shows the iterative history of the proposed method in standard normal space.

Table 2 Results of different approaches in Example 2

	G_p	$\mathbf{u}^*$	Iterations	Function evaluations
AMV	-----			
HMV	-2.2212	（-2.911，5.246）	114	456
CC $\lambda = 0.5$	-2.2290	（-3.116，5.127）	14	56
MCC Meng et al (2015)	-2.2162	（-2.860，5.275）	16	64
Proposed method $\lambda = 5$	-2.2293	（-3.108，5.132）	5	20

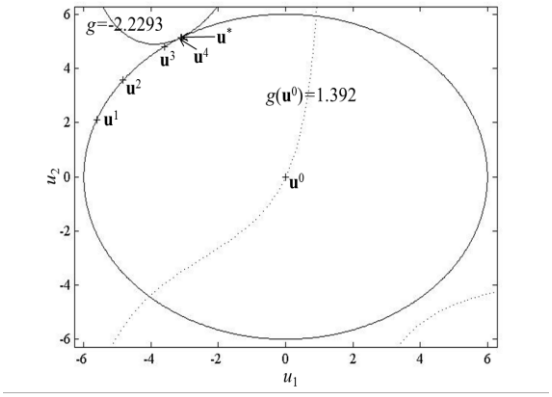

Figure 3 Iterative history in Example 2

Example 3 A performance function with high nonlinear degree is given as(Yang & Yi (2009)):

$$G(\mathbf{x}) = x_1^3 + x_1^2 x_2 + x_2^3 - 18$$

$$x_1 \sim N(10,5) \quad x_2 \sim N(9.9,5) \quad \beta_t = 3.0$$

The AMV method cannot converge while good results can be obtained using the proposed method with the step size adjusted automatically. Using initial step size $\lambda = 10.0$ and adjustment factor c=2.5, the iteration history is listed in Table 3. It can be seen that the step size λ is adjusted 7 times during 19 iterations and is decreased from 10 to 0.01638 finally. The iterative process converges to the MPTP accurately after 20 iterations. The probabilistic performance measure is $G_p = -76.035$ and the MPTP is $\mathbf{u}^* = (-1.0595, -2.8067)^T$. Compared with chaos control method(CC) in Yang & Yi (2009), which needs 95 iterations to converge, the proposed method is more effective.

Table 3 Iterative history of the proposed method in Example 3

Example 4 A slab-column structure is shown in Figure. 4. The structure is made of the same material with density 7.8e3 kg/m , elasticity modulus 2e11Pa and Poisson's ratio 0.3.The thickness of the slabs is 0.2 m. ANSYS is used to model and analyze the structure . The slabs are modelled by Shell63 elements and the columns are modelled by beam4 elements. The columns are fix supported at the bottom. The foursquare columns are divided into three segments by the slabs and the side lengths of the three segments are k_i*0.5 m (i=1,2,3). k_1, k_2 and k_3 are independent random variables and their stochastic information is given in Table 4. The performance function is $G = \omega_0 - \omega$, in which $\omega_0 = 4.1072$ Hz. The target reliability index is $\beta_t = 3.0$.

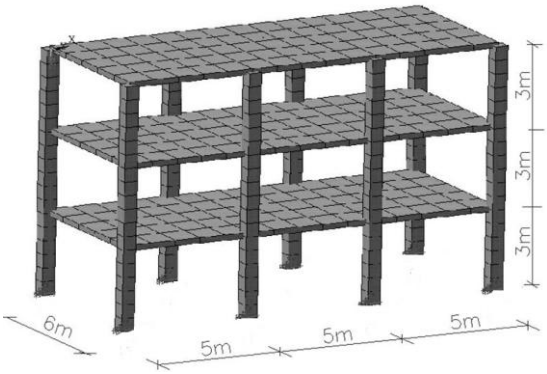

Figure 4 The slab-column structure

Table 4 The stochastic information for Example 4

Variable	Distribution	Mean	std. dev.
k_1	Normal	1.2962	0.2
k_2	Normal	0.9917	0.2
k_3	Normal	0.6627	0.2

The AMV method converged after 11 iterations and 46 function evaluations. The proposed method, with initial step size $\lambda = 50.0$ and adjustment factor c=2.5, converged after 6 iterations and 32 function evaluations. The obtained PPM is G_p=0.0159 and the MPTP is $\mathbf{u}^*$=(1.1931,1.1173,1.2403). The CC method converged to almost the same result after 15 iterations and 62 function evaluations. The results are listed in Table 5.

Table 5 Results using different methods in Example 4

	Iterations	Function Evaluations	G_p	$\mathbf{u}^*$
AMV	11	46	0.0163	(1.1955,1.0988,1.2444)
Proposed method	6	32	0.0159	(1.1931,1.1173,1.2403)
CC	15	62	0.0160	(1.1927,1.1042,1.2429)

CONCLUSIONS

When locating MPTP in PMA, the AMV method may converge very slowly, or oscillate and fail to converge if the performance function is highly nonlinear. In this paper an easy iterative algorithm, which introduces a "new" step size to control the convergence of the sequence, is proposed. This step size is new because it may be constant during the iteration or decreases successively several times during the whole iteration process using an easy self-adjust strategy. It is proved that the AMV method is a special case of this proposed algorithm when the step size tends to infinity. Numerical results of several nonlinear performance functions, including an engineering application, indicate that the proposed algorithm is effective and as simple as the AMV but more robust.

ABSTRACT

Severe damages of civil infrastructures under near-fault ground motions have impelled the community of earthquake engineering to pay intensive attention and investigation to their engineering characteristics and structural seismic effects. This paper reviews the recent research advances of authors in the engineering characteristics of near-fault ground motions and seismic responses and base-isolated performance analysis of building structures. Firstly, two non-structure-specific intensity measures, such as improved effective peak acceleration and velocity (*IEPA*, *IEPV*) were proposed. Two frequency content parameters were also suggested, namely the mean period of Hilbert marginal spectrum T_{mh}, and coefficient of variance of dominant instantaneous frequency of Hilbert spectrum H_{cov} which reflects the frequency nonstationary degree of ground motions. Meanwhile, a new stochastic model to synthesize near-fault impulsive ground motions with the feature of the strongest pulse was established. Then, the chaotic and fractal/multifractal characteristics of strong earthquake ground motions were analyzed deeply to explore their complexity from a novel perspective of nonlinear dynamics, and the inherent relation between fractal dimensions and period parameters of near-fault motions was exposed. Moreover, the mechanism of interstory deformation of tall building was illustrated based on engineering properties of pulse-like ground motions and generalized drift spectral analysis. Finally, the influence of ground motion properties on the seismic responses and performance of tall structures and base-isolated buildings was revealed.

Near-fault ground motions, intensity measures, frequency content parameters, chaotic and fractal characteristics, seismic performance of buildings.

INTRODUCTION

The engineering characteristics and structural seismic effects of near-fault ground motions have drawn much attention of many earthquake engineers since several destructive near-fault earthquakes, such as Northridge earthquake in 1994, Kobe earthquake in 1995, Chi-Chi earthquake, Taiwan in 1999, and Wen-Chuan earthquake in 2008 etc (Anderson and Bertero 1987; Hall *et al*. 1995; Somerville *et al*. 1997; Wang *et al*. 2002; Mavroeidis and Papageorgiou 2003; Bray and Rodriguez-Marek 2004; Liu *et al*. 2006; Tian *et al*. 2007; Zhai *et al*. 2008; Zhai *et al*. 2013). Generally speaking, near-fault ground motions are referred to the earthquake ground motions which are close to the rupture surface with the fault distance smaller than 20 km, and strongly depend on the rupture mechanism and obviously involve rupture forward directivity and fling-step effect. At present, there are numerous of theoretical and experimental studies on the analysis of seismic responses and dynamic performance in building and bridge engineering, including the base-isolated structures and energy dissipation structures subjected to near-fault ground motions (Alavi and Krawinkler 2004; Kalkan and Kunnath 2006; Yi and Zhang 2007; Tang *et al*. 2007; Zhao *et al*. 2008; Rupakhety and Sigurdsson 2011; Zamora and Riddell 2011; Ma *et al*. 2012; Li *et al*. 2012; Psycharis *et al*. 2013).

One of the most significant characteristics of great earthquake events is that the epicenters of earthquakes were close to the urban areas and the near-fault ground motions have distinct long-duration velocity and displacement pulses, which result in the high seismic intensity of downtown area. For example, in the Kobe earthquake in 1995, almost 90% of buildings located within the 5 km distance to the rupturing fault were collapsed or seriously damaged. In recent twenty years, engineering properties and structural effects of near-fault ground motions as well as the earthquake-resistant and vibration-reduction design of engineering structures have become important research topics in the field of engineering seismology and earthquake engineering. Meanwhile, the objective of these researches is to clarify the mechanism of structural seismic damage, and seek for effective strategies of structural seismic protection and thus develop relevant seismic design codes of civil

infrastructures. Seismic isolation of structure is a rapid developing technology for seismic protection, which has been applied widely in civil engineering. The base-isolated building presents a good performance of vibration-reduction in far-field region, but for the near-fault ground motions, the distinct long-duration velocity pulses may impose adverse influence on the seismic behavior and design of base-isolated buildings and other long-period structures. Moreover, note that the existing seismic design codes in many countries are developed based on the earthquake records not enough close to destructive faults, and the associated studies and understandings on damage potentials of near-fault ground motions with long-duration impulses are still insufficient.

This paper reviews the recent research developments of authors in the engineering characteristics of near-fault ground motions (Yang *et al*. 2009; Yang and Wang 2012; Yang *et al*. 2012; Yang and Zhang 2013; Yang and Long 2014; Yang *et al*. 2015, Yang and Zhou 2015) and seismic performance analysis of building structures (Yang *et al*. 2005; Yang *et al*. 2006; Yang *et al*. 2007; Yang *et al*. 2008; Yang *et al*. 2010; Jiang *et al*. 2010; Yang and Zhao 2010). In particular, two non-structure-specific intensity measures, i.e. improved effective peak acceleration and velocity (*IEPA*, *IEPV*) were proposed. Meanwhile, two frequency content parameters were advised, namely the mean period of Hilbert marginal spectrum T_{mh} and variance coefficient of dominant instantaneous frequency of Hilbert spectrum H_{cov}, and the nonlocal period parameters of near-fault ground motions were scrutinized. The stochastic modeling and synthesizing of near-fault pulse-like motions with forward directivity effect taking the orientation of the strongest pulses into account was addressed. Further, the chaotic and fractal properties of near-fault motions were explored form a new perspective of nonlinear dynamics. Moreover, it was shown that the velocity pulses of forward directivity and fling-step effect can excite different modal response of structures, and the mechanism of deformation distribution of tall building was illustrated as well. Finally, the influence of ground motion properties on seismic responses and performance of tall structures and base-isolated buildings was revealed.

INTENSITY AND PERIOD PARAMETERS OF NEAR-FAULT GROUND MOTIONS

The topic of engineering characteristics and structural effects of near-fault ground motions is becoming a research hotspot and important area in earthquake engineering, which plays a significant role in forming new field of this discipline and developing innovational technology of earthquake resistance and disaster mitigation. However, previous studies mainly focused on the characteristics of far-fault ground motions, and lacked the works examining deeply the properties of near-fault ground motions and seismic effects of structures.

Intensity measures of near-fault ground motions

Considering the frequency property of near-fault ground motions with rich long-period contents, Yang *et al*. (2009) proposed two improved intensity measures, namely, improved effective peak acceleration (*IEPA*) and improved effective peak velocity (*IEPV*). They are expressed as:

$$IEPA = \frac{S_a(T_{PA} - 0.2\,\mathrm{s}, T_{PA} + 0.2\,\mathrm{s})}{2.5} \tag{1}$$

$$IEPV = \frac{S_v(T_{PV} - 0.2\,\mathrm{s}, T_{PV} + 0.2\,\mathrm{s})}{2.5} \tag{2}$$

in which $S_a(T_{PA}-0.2\mathrm{s}, T_{PA}+0.2\mathrm{s})$ represents the mean 5%-damped spectral acceleration in the period range of $T_{PA}-0.2$s and $T_{PA}+0.2$s, and the length of interval is 0.4 s as the same as the definition in ATC-3 code; $S_v(T_{PA}-0.2\mathrm{s}, T_{PA}+0.2\mathrm{s})$ denotes the mean 5%-damped spectral velocity in the period range of T_{PV}.

Then, 150 near-fault earthquake records including pulse-like ground motions from two different earthquake events, Chi-Chi earthquake and Northridge earthquake were chosen. The correlation between 30 intensity indices of the near-fault ground motions and dynamic responses (i.e., maximum displacement, input and hysteretic energy) of bilinear single degree of freedom (SDOF) systems were examined. The numerical results indicate that the correlation between intensity indices of near-fault ground motions and structural responses are related to the fundamental period of structures. Generally speaking, the acceleration-related intensity parameters (*PGA*/Peak Ground Acceleration, *IEPA* and I_a) have a strong correlation with demand parameters or dynamic responses of short-period SDOF systems, and the velocity-related parameters (*IEPV*, I_F and *PGV*/Peak Ground Velocity) present good correlation with demand parameters of SDOF systems with the medium-period and medium-long-period. For the long-period systems, displacement-related parameters (I_d, d_{sq} and P_d) are fairly correlated with demand parameters. Moreover, the *IEPA* and *IEPV* of near-fault ground motions improve the performance of intensity measure of conventional parameters, i.e., *EPA* and *EPV*, respectively. Compared with the Northridge earthquake the long-period impulsive feature of Chi-Chi earthquake is more remarkable due to

the different source mechanism. There are considerable differences in the correlation curves of intensity measures of impulsive and non-pulse ground motions, especially for Chi-Chi records.

Nonlocal period parameters of near-fault ground motions

Hilbert-Huang transformation is a new time-frequency signal analysis method, which can be applied to investigate the time-variant non-stationary frequency property of near-fault ground motions. Using HHT to analyze the representative near-fault records, the variance coefficient of predominant instantaneous frequency of Hilbert spectrum (H_{cov}) was suggested to reflect the non-stationary degree of frequency contents of ground motion (Yang and Wang 2012):

$$H_{\mathrm{cov}} = \frac{\sigma(\omega(t))}{\mu(\omega(t))} \tag{3}$$

Eq. 3 means that H_{cov} equals the ratio of standard deviation to mean value of time history of predominant instantaneous frequency of Hilbert spectrum $\omega(t)$ in the whole duration of ground motion. It can be seen from the definition that the non-stationary degree of ground motion's frequency increases with the variance coefficient H_{cov}.

Meanwhile, considering that the Hilbert marginal spectrum can describe the frequency content of strong ground motions better than Fourier amplitude spectrum, we defined similarly the mean period of Hilbert marginal spectrum (T_{mh}) by Hilbert marginal spectrum (Yang and Wang 2012), namely,

$$T_{mh} = \frac{\sum_i H_i^2 \left(1/f_i\right)}{\sum_i H_i^2} \qquad 0.2\mathrm{Hz} \le f_i \le 25\mathrm{Hz} \tag{4}$$

where H_i stands for the Hilbert marginal spectrum coefficient, and f_i is the discrete frequency.

Subsequently, 46 near-fault ground motion records from Chi-Chi earthquake are grouped into several categories with different motion characteristics, and 7 period parameters characterizing frequency contents of ground motion are calculated, including the mean period of Fourier amplitude spectrum T_{m}, mean period of Hilbert marginal spectrum T_{mh}, characteristic period of acceleration response spectrum T_{c}, the predominant period T_{PA} and T_{PV} of 5%-damped acceleration and velocity response spectrum, etc. Furthermore, the variance coefficient of predominant instantaneous frequency of Hilbert spectrum is also obtained. It is demonstrated that the non-stationary characteristic of near-fault ground motions is significant, and the variance coefficient H_{cov} of predominant instantaneous frequency of Hilbert spectrum clearly reflects the non-stationary property and degree of ground motion's frequency. In addition, the influence of motion characteristics of near-fault records on their frequency content parameters and non-stationary property is analyzed.

A stochastic model and synthesis of near-fault impulsive ground motions

When considering the pulse-like motions and their seismic responses, the orientation of ground motions are paramount (Zamora and Riddell 2011; Shahi 2013). The combination of continuous wavelet transform coefficients from two horizontal and orthogonal components of a ground motion record is utilized to yield the orientation of its strongest pulse. According to the statistical parametric analysis of velocity time histories in the orientation of the strongest pulse, a new stochastic pulse model (Yang and Zhou 2015) with a specified magnitude and various fault distances R was established as follows

$$V_p(t) = PGV \cdot \exp\left[\sigma_{\ln PGV} - \frac{\pi^2}{4}\left(\frac{t-T_{pk}}{N_c T_p}\right)^2\right] \cdot \cos\left(2\pi \frac{t-T_{pk}}{T_p} - \varphi\right) \tag{5}$$

$$\ln(PGV) = 4.39 - 0.14 \ln R \tag{6}$$

where T_p, V_p, N_c, T_{pk} and φ represent the pulse period, peak pulse velocity, number of circles in the pulse, the location and phase of the pulse, respectively, which have a clear physical interpretation. These pulse parameters are estimated by nonlinear least-square fit of the single Gabor wavelet in Eq. 5 to the velocity time history with the strongest pulse. Meanwhile, the correlations between pulse parameters and seismological parameters are analyzed, and different regression models are adopted to fit those correlated parameters. The standard deviations together with those uncorrelated parameters are regarded as random variables, which follow well the normal or lognormal distributions based on the statistical analysis.

Finally, acceleration time histories of ground motions with high- and low-frequency components are generated by the superposition of the stochastic pulse and the stochastic high-frequency accelerogram modulated by an

intensity envelope function. The synthesized ground motions indicate that the proposed stochastic model can reflect the pulse characteristic of near-fault ground motions. Additionally, the dynamical reliability of frame building under random near-fault pulse-like excitations generated from the stochastic model is addressed.

CHAOTIC AND FRACTAL PROPERTIES OF NEAR-FAULT GROUND MOTIONS

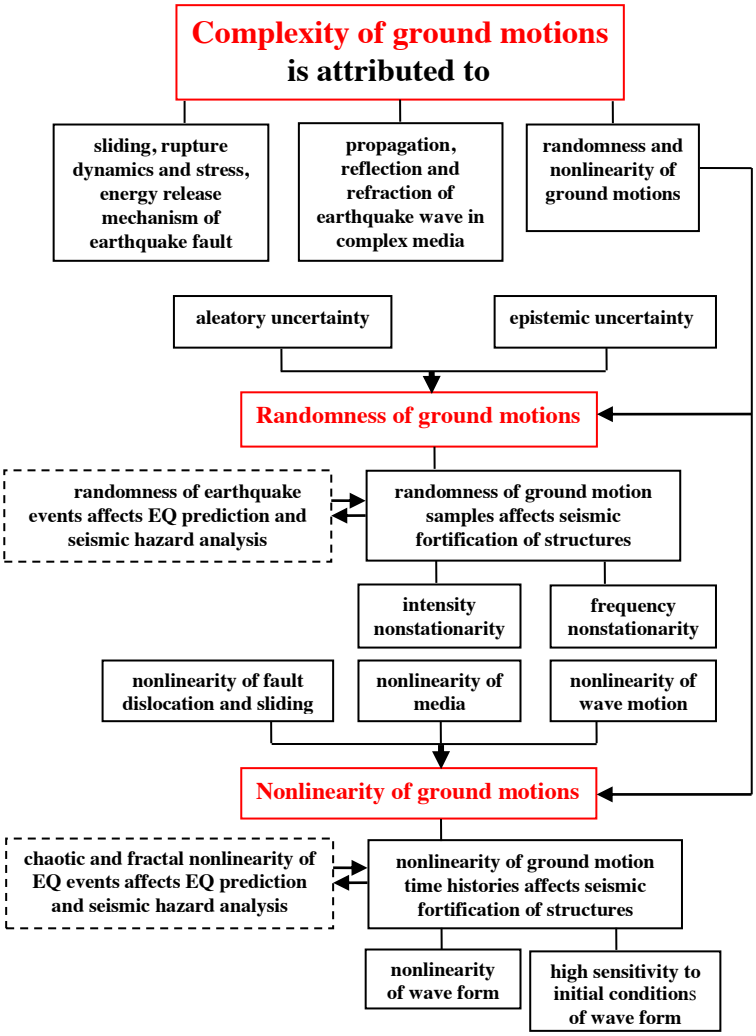

Figure 1 Complexity of earthquake ground motions

In fact, at present the two issues of earthquake engineering in near-fault region are closely connected with the two difficulties or challenges emerged in the development of earthquake engineering. One difficulty is the complexity of earthquake ground motions, and another is the complexity of damage failure of engineering structure. The complexity of structural failure is shown as diverse failure modes and failure behaviors, in which the reasons contain the plastic deformation of materials and components, the degradation of strength or stiffness, hysteretic energy dissipation, damage accumulation, low-cycle fatigue, crack extension, frictional contact, buckling instability, etc. The complexity of earthquake ground motions is attributed to various factors, such as sliding, rupture dynamics and stress and energy release mechanism of earthquake fault, propagation, reflection and refraction of earthquake wave in complex media, and the randomness and nonlinearity of ground motions at engineering site, etc. A number of ground motion samples recorded in single or multiple earthquake events generally exhibit the randomness. Also, the multiple earthquake events occurred at the same or different sites present the stochasticity. The randomness of ground motion samples and earthquake events is mutually affected and correlated. The randomness of earthquake events incurs a great difficulty to earthquake prediction and seismic hazard analysis, while the randomness of ground motion samples produces a challenge to seismic fortification of engineering structures. Generally, the randomness of ground motion samples refers to the nonstationarity of intensity and frequency content of ground motions as stochastic processes. The power

spectrum model of ground motions suitable to random vibration analysis of structures can characterize well the intensity nonstationarity of ground motions, but it is still necessary to further develop a fully time-frequency non-stationary model of ground motions for random vibration analysis. The randomness of ground motions is originated from the aleatory and epistemic uncertainty. Since Housner established the white-noise stochastic model of earthquake ground motions in 1947, the researchers usually regard the ground motions as a kind of stochastic process, which is related to that the probability and statistics theory dealing with the random uncertainty issues was developed quite maturely in 1940s.

Nevertheless, another aspect of complexity of earthquake ground motions, namely nonlinearity, has been ignored for a long time in earthquake engineering, which is associated with a fact that nonlinear dynamics theory was developed until 1980s. Many ground motions recorded in single or multiple earthquake events present the nonlinearity. Meanwhile, the multiple earthquake events occurred at the same or different sites exhibit the nonlinearity. The nonlinearity of ground motions and earthquake events is also mutually affected and correlated. The nonlinearity of chaotic and fractal properties of earthquake events imposes a great difficulty to earthquake prediction and seismic hazard analysis, while the nonlinearity of ground motions produces a challenge to seismic fortification of structure. The nonlinearity of time history of ground motions is shown in: (1) the waveform of time history of ground motions is nonlinear, which cannot be linearly superimposed by simple harmonic waves; (2) the waveform of time history of ground motions is highly sensitive to initial condition, and waveforms of ground motion records from different stations with the near distances in the same earthquake event and those from the same station in different earthquake events with short time interval present remarkable distinction. In practice, earthquake ground motions are the site output response of nonlinear dynamical system of geophysics, and their strong nonlinearity comes from the nonlinearity of initial condition of earthquake dynamic process and dynamic model, including the nonlinearity of fault dislocation and sliding, the nonlinearity of media and wave motion etc. Currently, the wavelet transform and Hilbert-Huang transform appropriate for nonlinear and non-stationary time series analysis are widely used in the characteristics analysis of ground motion time histories and structural seismic responses.

Recently, Yang *et al*. (2012) examined the nonlinear dynamical property of acceleration time histories of near-fault ground motions by introducing the method of chaotic time series analysis. Based on the approach of power spectrum analysis, principal component analysis and improved false nearest neighbor (FNN) method, it is qualitatively illustrated that the ground motion acceleration series possess the chaotic property. Then, the method of chaotic time series analysis is applied to quantitatively calculate the nonlinear characteristic parameters such as correlation dimension and maximal Lyapunov exponent. Computational results indicate that the strong earthquake ground motions have the chaotic characteristic, which are not the pure random signal. The high irregularity and complexity of ground motions are the reflection of strong nonlinearity of earthquake physical process.

On the other hand, Yang and Zhang (2013) investigated the complexity and irregularity of near-fault ground motions from the viewpoint of fractal geometry. The box-counting fractal dimensions of 30 acceleration time histories of near-fault ground motions from the Chi-Chi and Northridge earthquakes are calculated. It is shown that the acceleration time histories of ground motions exhibit the statistical fractal property, and the effect of characteristic of near-fault motions on their fractal dimensions is remarkable. The average fractal dimension of near-fault impulsive ground motions with forward directivity effect is middle, and that of impulsive ground motions with fling-step effect is the smallest, while the average fractal dimension of non-pulse ground motions is the largest and the corresponding irregular degree of waveforms is the highest. Moreover, the fractal dimension of ground motions reflects their frequency property, and can be regarded as an index to represent their period. The fractal dimension D of ground motions is negatively correlated with their characteristic period T_c. In addition, the fractal property of the seismic dynamic responses of SDOF systems under near-fault ground motions is examined. Finally, based on multifractal detrended fluctuation analysis, the multifractal characteristic parameters of acceleration time series for typical near-fault ground motions are calculated (Yang *et al*. 2015). It is illustrated that the scaling exponent $h(2)$ can be utilized to measure the frequency content and irregularity degree of strong earthquake ground motions, and the long-range correlation of small and large fluctuation is the major source of multifractality of near-fault ground motions.

SEISMIC PERFORMANCE ANALYSIS OF BUILDINGS UNDER NEAR-FAULT MOTIONS

Deformational distribution feature and mechanism analysis of buildings subjected to near-fault pulse-type ground motions

Based on the method of generalized interstory drift spectral analysis, the tall building is equivalently expressed as a shear-flexural beam shown in Figure 2, and the interstory drift ratios (IDR) of typical shear-flexural beams

are exhibited in Figure 3 (Yang *et al*. 2010). Ground inputs include the idealized simple pulses and three groups of near-fault records with forward directivity pulses, fling-step pulses and without pulse. The features of deformational distribution of buildings along height subjected to near-fault motions are acquired. It is illustrated that for moment-resisting frame buildings, the fling-step pulses excite primarily their contribution in the first mode and generate large deformation in the lower stories. The forward directivity pulses can activate the drift response of higher modes of frame buildings. Moreover, the mechanism for these deformational phenomena of building are revealed according to the distinct property of near-fault pulse-type ground motions and generalized drift spectral analysis. It is pointed out that the difference among the average interstory drift spectra of three groups of ground motions is remarkable in the whole range of fundamental period.

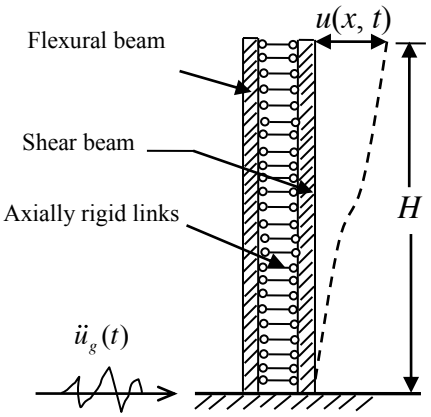

Figure 2 Shear-flexural beam model used in interstory drift spectrum analysis

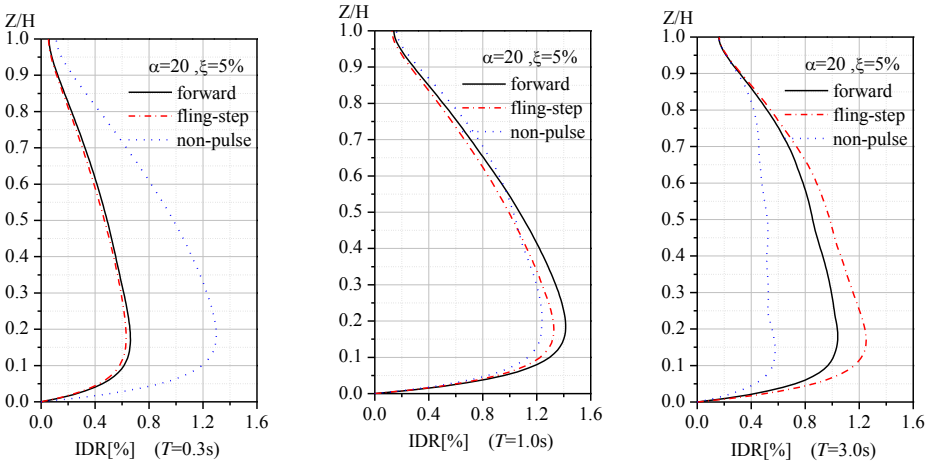

Figure 3 Mean IDR distribution of buildings under three groups of near-fault ground motions with fundamental periods T=0.3 s, 1.0 s, 3.0 s

Influence of near-fault ground motions on seismic responses of tall building with short-limb wall

Near-fault ground motions have the unique characteristics of hanging wall effect, rupture directivity effect, and large velocity pulse. The effect of ground motions with these features on the seismic responses of tall building with short-limb walls was examined in Yang *et al*. (2008). The near-fault recordings from Chi-Chi, Taiwan earthquake are selected as the input and the ANSYS software is used to establish a spatial bar-shell combined finite element model for one 12-story tall building with short-limb walls in Figure 4, then the elastoplastic time history analysis of this mode is implemented. The calculated results show that the hanging wall and rupture directivity effect can remarkably amplify the dynamic responses of structural system with short-limb walls, and the maximum drift ratio 0.98% occurs at the 5th story in the middle of building, which means that the building reaches medium damage state. Moreover, the effect of pulse-like ground motions highly depends on the structural period, and the pulse-like effect on the long-period structure is significant.

Note: *PGD* stands for peak ground displacement, *d* is the fault distance, t_d is the 95% significant duration, and the data in the bracket represent static displacement of ground motions with fling-step pulses.

The influence of two kinds of near-fault ground motions with different velocity pulses due to forward directivity and fling-step effects on the seismic responses of high-rise steel frame structure was scrutinized in Jiang *et al*. (2010). Near-fault ground motions with forward directivity and fling-step pulses and without velocity pulse are chosen as seismic inputs as shown in Table 1, and the velocity and displacement time histories of near-fault ground motion RRS228 with forward directivity pulse and TCU052 NS with fling-step pulse are demonstrated in Figures 5 and 6, respectively. The SAP2000 software is applied to model a 20-story plane frame structure, and the elastoplastic time history analysis of structure are implemented. Computational results illustrate that the

ground motions with fling-step and forward directivity pulses mainly activate the fundamental modal response of the 20-story steel building, and thus lead to the larger IDR in the lower story and global collapse, while the non-pulse ground motions can excite the response of higher modes. Furthermore, the structural damage potential of impulsive ground motions is significantly greater than that of non-pulse ground motions. Numerical results of dynamic responses and damage state of steel frame structure are explained rationally from the perspective of energy dissipation of SDOF system.

Figure 6 Velocity (a) and displacement (b) time histories of near-fault motion TCU052 NS with fling-step pulse

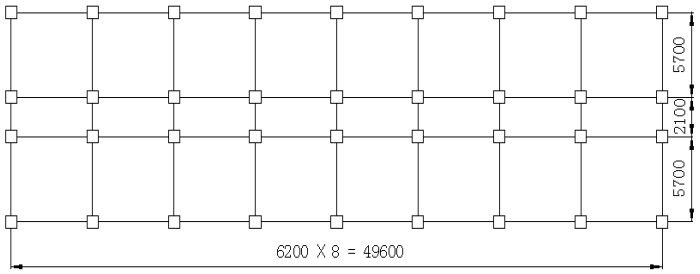

Figure 7 Plan of base-isolated building structure

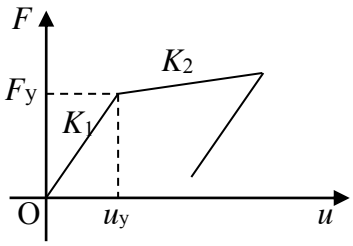

Figure 8 Bilinear hysteretic model of lead rubber bearings

In addition, near-fault ground motion records listed in Table 1 were also selected as seismic inputs, and the influences of forward directivity pulses and fling-step pulses on the seismic performance of SDOF system and base-isolated building with lead rubber bearings were examined in Yang and Zhao (2010). Six-story reinforced concrete base-isolated frame and bilinear hysteretic model of lead rubber bearings are shown in Figures 7 and 8, separately. The response spectrum analysis illustrates that the effects of rupture forward directivity and fling step of ground motions on the seismic responses of engineering structure are period-dependent. In the range of short and medium period, the spectral acceleration of ground motions with forward directivity effect is larger than that with fling step effect. In the long period range, the spectral acceleration of motions with fling step is generally larger than that with forward directivity. Furthermore, compared with the non-pulse ground motions, the dynamic responses of base-isolated buildings under the ground motions with rupture forward directivity and fling-step pulses are increased significantly. Moreover, the velocity pulses from fling-step effect remarkably amplify the interstory drift and shear force of base-isolated building at lower stories. This implies that the fling-step pulses cause more severe damage to long-period buildings than the forward directivity pulses.

CONCLUSIONS

This paper summarized the research advances of authors in engineering characteristics of near-fault ground motions as well as seismic performance of tall and base-isolated buildings under near-fault motions. Two non-structure-specific intensity measures, namely improved effective peak acceleration and velocity (*IEPA*, *IEPV*) were proposed. Meanwhile, two frequency content parameters were suggested, i.e., the mean period of Hilbert marginal spectrum T_{mh}, and coefficient of variance of dominant instantaneous frequency of Hilbert spectrum H_{cov} which reflects the frequency nonstationary degree of ground motions. Further, a new stochastic model to synthesize near-fault impulsive ground motions with the feature of the strongest pulse was constructed. Then, the chaotic and fractal/multifractal characteristics of strong earthquake ground motions were analyzed to explore their complexity from a novel viewpoint of nonlinear dynamics, and the inherent relation between fractal dimensions and period parameters of near-fault motions was exposed. Moreover, the mechanism of interstory deformation of tall building was illustrated based on engineering properties of impulsive ground motions and generalized drift spectral analysis.

However, the studies on seismic analysis and vibration-reduction design of high-rise building structures under stochastic excitations of near-fault ground motions are very scarce relatively, which hamper the development of performance-based earthquake engineering and seismic design code of structures. On the other hand, the improvement of the theories of seismic structures poses an urgent need to the profound research in this area. Therefore, conducting the research in seismic performance analysis and optimal vibration-reduction design of high-rise buildings under near-fault strong ground motions has important theoretical significance and potential of engineering application, and the further study on this line is worthy.

ABSTRACT

This paper describes the three-dimensional seismic vulnerability assessment of a high-rise steel moment-frame setback tower, designed and detailed per the 2010 ASCE7 and 2010 AISC-341. The performance evaluations are conducted based on nonlinear history analyses under a set of multi-directional strong ground motion records which are scaled to maximum considered earthquake spectrum in accordance with ASCE41-13. Plastic hinge monotonic and hysteretic behavior for prequalified steel reduced beam section connections are obtained from values presented in TBI Guidelines and PEER/ATC72. Hysteretic behaviors are adjusted based on FEMA P440A recommendations to incorporate stiffness and strength degradation in analyses. Plastic rotation demands of the order of 2-4% of a radian and inter-story drift/residual demands close to the order of 0.03/0.01 are created on the basis of median of the records. These values almost coincide to performance at or near 'collapse prevention' reported in TBI Guidelines. This performance level clarifies the accuracy of response modification coefficient presented in ASCE7-10 for special moment resisting frames. The well-distributed yield pattern along building's height implies the superior contribution of lateral force-resisting system to control dynamic instability.

KEYWORDS

Performance-based design, high-rise building, moment resisting frame, nonlinear history analysis.

INTRODUCTION

Nowadays Performance-Based Seismic Design Procedures (Tall Building Initiatives, TBI, 2010) are introduced for high-rise buildings as recommended alternatives to the prescriptive strategies for seismic design of new buildings encompassed in standards such as ASCE7-10 (2010). The main reasons why the alternatives have been developed are generally related to either height limits or uncovered seismic-force-resisting systems in accordance with the Building Codes. Elaborated structural and earthquake knowledge about selection and scaling of ground motions, reliable mathematical modelling and nonlinear history analyses, are the prerequisites for proper implementation of TBI guidelines. In TBI guidelines, acceptable criteria is determined according to two hazard levels including service level earthquake (SLE) and maximum considered earthquake (MCE). In SLE, the initiation of repairable damage is considered to obtain structural limit states, while in MCE, the onset of considerable strength and stiffness degradations in structural components are presumed with low probability of overall or local collapse.

Design and acceptable seismic performance of a concrete core-wall high-rise building was evaluated by Yang *et al*. (2012) based on two alternative approaches in accordance with International Building Code (IBC 2006) and TBI guidelines. The results indicated appropriate performance of the structural system. Different design procedures in terms of code-compliant design and performance-based design for a 40-story buckling-restrained brace frame were compared by Jones and Zareian (2013). The structural performance objectives are assessed on the basis of inter-story drift ratio (IDR) exceedance from allowable values. Performance-based evaluation of ultra-high-rise building designed beyond code-specified provisions was studied by Wei *et al*. (2012) and the results demonstrated that performance design are reliable to predict structural response in severe earthquakes.

In this paper seismic performance of a case study high-rise moment-frame with setback irregularity is assessed based on the TBI recommended criteria for MCE hazard level. The major objective of this assessment is to validate collapse safety margin as declared by ASCE7-10. This objective is gained by using nonlinear history analyses to estimate the response of the high-rise tower to a set of ground motions that are scaled to MCE shaking as reported in TBI guidelines. Despite the fact that this evaluation does not offer quantifiable margin against collapse it demonstrates under selected ground motions forces and deformations are not beyond acceptable limits.

A CASE STUDY BUILDING DESCRIPTION

Selected building is comprised of two similar legs with approximate height of 240 meters (50 story) connected together in top stories (Figure 1 (a)). These legs are architecturally designed for residential and hotel occupancy called 'Apartment Part' and 'Hotel Part', respectively. This building was architecturally designed by ATKINS Group with typical story height of 4 meter, while ground and podium floors have level height of 6 meter. Because the building is located in earthquake-prone region, site-specific investigations are carried out to obtain design spectrum. The structural designs were carried out by engineering research group knowledgeable in seismic design of high-rise buildings. Response spectrum analysis (RSA) on the basis of design-based spectrum is conducted on three dimensional elastic model of the building using commercial program CSI-ETABS (2013). The three dimensional view of the structural model is shown in Figure 1 (b). In Figure 2 (a), typical floor plan of the building is illustrated. Design parameters according to ASCE7-10 are adjusted to obtain minimum gravity and lateral loads appropriate for the building design. Special moment resisting frames (SMRFs) are adopted to resist against both gravity and lateral loads. The arrangement of moment resisting connections in one portion of the floor plan is depicted in Figure 2 (b). Gravity load bearing system is comprised of composite slab including metal deck, corrugated sheets of 1 mm, and concrete slab of 140 mm thickness supported by steel joists connected to beams or columns. Beam sections were sized with I-shape built-up sections while column sections were proportioned with H-shape built-up sections in accordance with Load Resistance Factor Design (LRFD) of ANSI/AISC 360-10 (2010) and seismic detailing is provided by requirements developed in ANSI/AISC341-10 (2010). Prequalified Reduced Beam Section (RBS) connections are detailed in accordance with ANSI/AISC341-10 to resist against lateral loads. All requirements such as strong column- weak beam and panel zone strength are accounted during design process.

It is noteworthy that structural concrete walls are arranged through first five stories of the building to reduce flexural demands on steel column base plates. As can be observed in Figure 1 (a), a structure called 'Top Hat' is located on top of the apartment and hotel parts of the building due to the architectural reasons. The structure has to be continuous in the 'Top Hat' area to accommodate façade requirements in the finishing of the architectural form. ASTM-A36, Grade 36 and ASTM-A572, Grade 50 steel is used for the beams and columns in the building, respectively. It is assumed that the nominal yield stress is 248.21 Mpa and 344.73 Mpa for A36 and A572, respectively. Additionally, the nominal ultimate stress is 399.90 Mpa and 448.15 Mpa for A36 and A572, respectively. The compressive strength of concrete is set to 30 Mpa for structural walls and floor slabs.

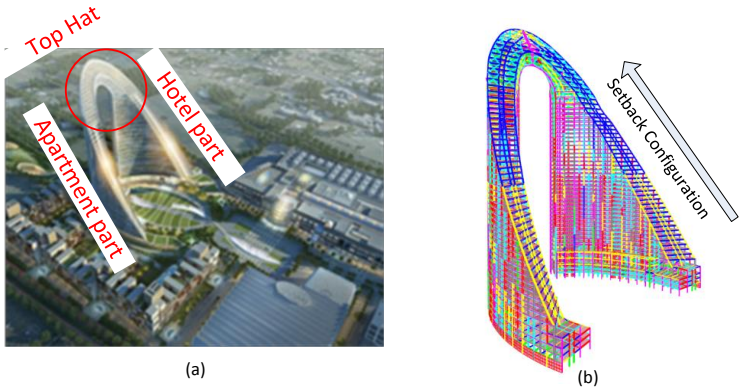

Figure 1 (a) Architectural rendering (b) 3-D ETABS model

SELECTION OF GROUND MOTION RECORDS

Ground motions for nonlinear response history analysis (NLRHA) are selected from PEER NGA database (2014). These records, as reported in Table 1, include classes from moderate earthquakes (Mw=6.5) to very large earthquakes (Mw=7.9). Several requirements for selecting and scaling of ground motions based on the recommendations reported in TBI guidelines including; controlling of seismic hazard conditions, compliance with site conditions and matching with the target spectrum (MCE spectrum) are taken into account. According to ASCE41-13 (2013), spectral-matching is adjusted to match frequency contents of accelerograms in which the response spectrum is within predefined limits of the MCE spectrum over the defined period range $0.2T_0$ to $1.5T_0$, where T_0 is the fundamental period of vibration (Figure 3(a)). Spectral matching is recommended by TBI for tall buildings rather than amplitude matching procedure as a result of reducing dispersion of response values. In

Figure 3 (b), the dispersion in the results is depicted by dashed lines with one and two times of standard deviation (SD) around median values.

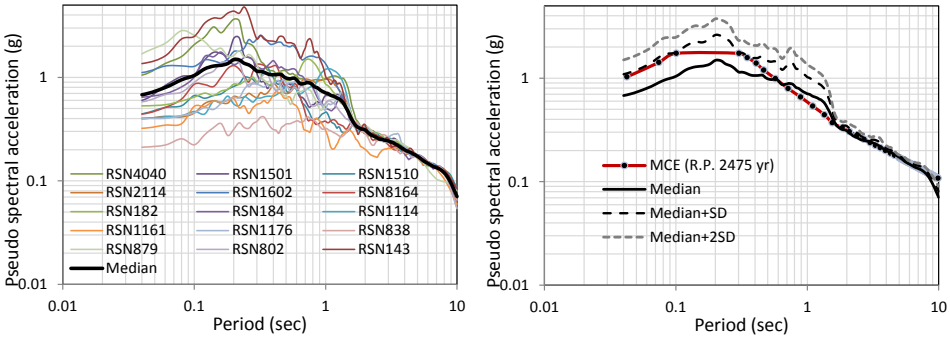
EXPLANATION OF THE ANALYTICAL MODEL

CSI-SAP2000 (2010), a general purpose finite element program, are utilized to simulate analytical model of the structure for NLRHA. The software is well-equipped to solve nonlinear equations of motion in structural systems with extensive number of degrees of freedom. One-way load transfer from floors to beam elements is considered and the floor slab contribution in stiffness and strength of the structure is excluded. Leaning column with no lateral stiffness is modeled to capture p-delta effects during lateral displacement. Load combination for p-delta effects are considered by 1.00 times dead loads plus 0.25 live loads according to TBI guidelines. Stiffness and mass proportional Rayleigh damping are specified as 2.5% for the periods at 6 and 1 second.



(a) (b)

Figure 3 Spectrum-matched ground motion records (a) spectral-matched record set (b) comparison between MCE spectrum and median, median+1SD, and median+2SD

As stated previously, RBS connections are adopted to provide required stiffness and strength against lateral load. Fiber-hinge elements are utilized to model flexural hinging in the RBS region nearby column face. To capture all important deterioration modes regarding lateral torsional buckling modes in steel components, artificial limits are imposed on stress-strain curves of each fiber model, as stated in TBI guidelines. Nonlinear parameters for modeling inelastic springs in beams are obtained from recommendations reported in PEER/ATC72 (2010) and FEMA P440A. Following equations are implemented to obtain backbone curve modeling parameters based on material and geometric characteristics of beam cross sections:

$$\theta_p = 0.19.\left(\frac{h}{t_w}\right)^{-0.314}.\left(\frac{b_f}{2t_f}\right)^{-0.10}.\left(\frac{L_b}{r_y}\right)^{-0.1185}.\left(\frac{L}{d}\right)^{0.113}.\left(\frac{d}{0.5334}\right)^{-0.76}.\left(\frac{F_y}{344.83}\right)^{-0.07} \quad (1)$$

$$\theta_{pc} = 9.62.\left(\frac{h}{t_w}\right)^{-0.513}.\left(\frac{b_f}{2t_f}\right)^{-0.863}.\left(\frac{L_b}{r_y}\right)^{-0.108}.\left(\frac{F_y}{344.83}\right)^{-0.36} \quad (2)$$

$$\Lambda = \frac{E_t}{M_y} = 592.\left(\frac{h}{t_w}\right)^{-1.138}.\left(\frac{b_f}{2t_f}\right)^{-0.632}.\left(\frac{L_b}{r_y}\right)^{-0.205}.\left(\frac{F_y}{344.83}\right)^{-0.391} \quad (3)$$

where h/t_w: ratio of depth to web thickness of the cross section, L_b/r_y: ratio of unbraced length to radius of gyration about the weak axis of the cross section, $b_f/2t_f$: ratio of flange width to thickness of the cross section, L/d: ratio of shear span to depth of the cross section, F_y: yield strength of the flange in Mpa, θ_p: pre-capping plastic rotation for beams with RBS connections, θ_{pc}: post-capping plastic rotation for beams with RBS connections, Λ: reference cumulative plastic rotation for beams with RBS connections. E_t: reference hysteretic energy dissipation capacity, and M_y: yield moment strength. The process of obtaining a backbone curve using the parameters defined above is illustrated in Figure 4 (a).

To validate analytical model with experimental results, an experimental test of steel RBS moment connection which was reported in literature (Uang *et al*. 2012) is taken into account. Standard loading protocol are considered, shown in Figure 4 (b). A typical comparison between experimental results and analytical model is shown in Figure 4 (c). As can be observed, the analytical result matches the experimental result reasonably well in the medium to large hinge rotation.

RESULTS AND DISCUSSIONS

According to TBI guidelines both global structural response including IDRs and residual drift ratios (RDRs) and local deformation-controlled actions in each component shall not exceed acceptance criteria while analytical model of the building are subjected to ground motions scaled to MCE level.

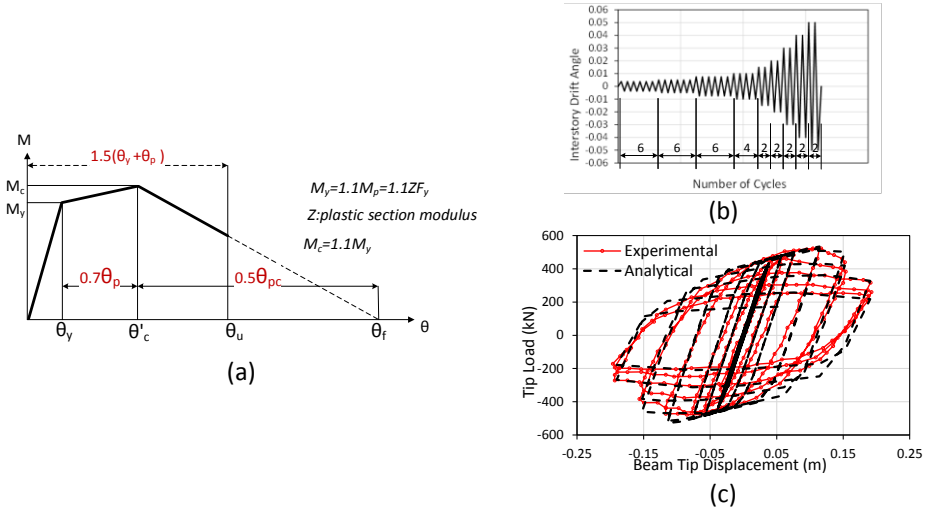


Figure 4 (a) Hinge backbone curve (b) standard loading protocol (c) calibration based on the standard loading protocol

Peak transient story drift

TBI declares that the mean of the absolute values of the maximum transient drift ratios from the set of analyses in each story level shall not exceed 3%. Additionally, the absolute value of the maximum story drift ratio from the set of analyses shall not exceed 4.5%. The heightwise profile of the absolute values of mean/maximum of maximum IDR histories obtained from NLRHAs in orthogonal directions (X, Y directions) along with SRSS values for the 'Apartment Part' and 'Hotel Part' are shown in Figure 5 (a)/(b) and Figure 6 (a)/(b), respectively. It is noteworthy that the SRSS values are calculated by the following relationship (Magliulo & Ramasco (2007)):

$$SRSS\left(E_x(t_i), E_y(t_i)\right) = \sqrt{\left(E_x(t_i)\right)^2 + \left(E_y(t_i)\right)^2} \quad (4)$$

where $E_x(t_i)$, $E_y(t_i)$ are demands in the X and Y directions at the i th instant of the time history. As can be observed, the maximum of maximum (Max-Max) IDRs is less than the value of 4.5% and the mean of maximum (Mean-Max) IDRs do not exceed the value of 3% according to the TBI guidelines. The scattering of the Mean-Max IDRs along the height of the building is visualized by vertical segments having the length twice the standard deviation in Figure 5 (c) and Figure 6 (c) for apartment and hotel parts, respectively. Dispersion of the results are more significant in lower stories and in some parts of upper stories (around floor 39). In lower stories, concentration of dispersed IDRs is attributed to p-delta effects while sudden jump of IDRs in upper stories is associated with the higher mode and the 'Top Hat' effects in combination. On the other hand, the dispersion of the IDRs in intermediate stories is almost uniform, indicating less influence of ground motion frequency contents on the IDR variations.

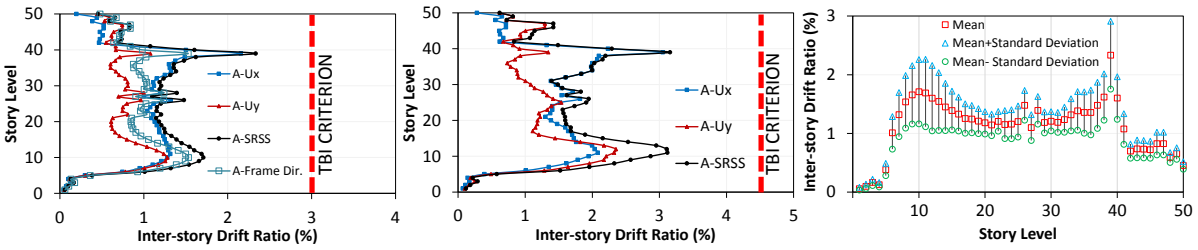

Figure 5 IDRs for 'Apartment Part' (a) Mean-Max IDR histories from different ground motions versus story level (b) Max-Max IDR histories from different ground motions versus story level (c) mean, mean+1SD, and mean-1SD of maximum IDRs

In Figure 5 (a) the results of drifts for the tallest frame in the building (selected frame in Figure 1 (a)) in the radial direction are also compared to those obtained from displacements at X and Y directions. As can be observed, the differences between interstory drifts obtained from the tallest frame in radial direction and

those obtained from plan displacements in X and Y directions are attributed to the participation of other frames in the lateral response.

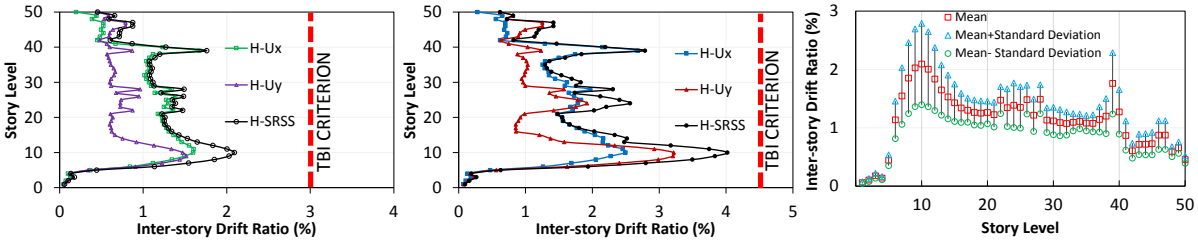

Figure 6 IDRs for 'Hotel Part' (a) mean of maximum IDR histories from different ground motions versus story level (b) maximum of maximum IDR histories from different ground motions versus story level (c) mean, mean+1SD, and mean-1SD of maximum IDRs

Residual story drift

RDRs may cause excessive post-earthquake displacements in the building and postpone the immediate operation after earthquake events. According to TBI guidelines, the mean of the absolute values of RDRs from s set of ground motions scaled to MCE level shall not exceed 1% in each story level, while this limiting value reach to 1.5% for maximum of the absolute values of RDRs in any analyses. The heightwise distribution of the absolute values of Mean-Max/Max-Max RDRs obtained from NLRHAs in orthogonal directions (X, Y directions) along with SRSS values for the 'Apartment Part' and 'Hotel Part' are shown in Figure 7 (a)/(b) and Figure 8 (a)/(b), respectively. Values of permanent drifts corresponding to Mean-Max and Max-Max RDRs are justifiably less than the limiting values reported in TBI guidelines. Similar to the IDR results, mean of the maximum RDRs is more scattered near both lower and upper stories as observed in Figure 7 (c), Figure 8 (c). The result again accentuates p-delta and higher mode effects as two dominant modes of response for the building under study.

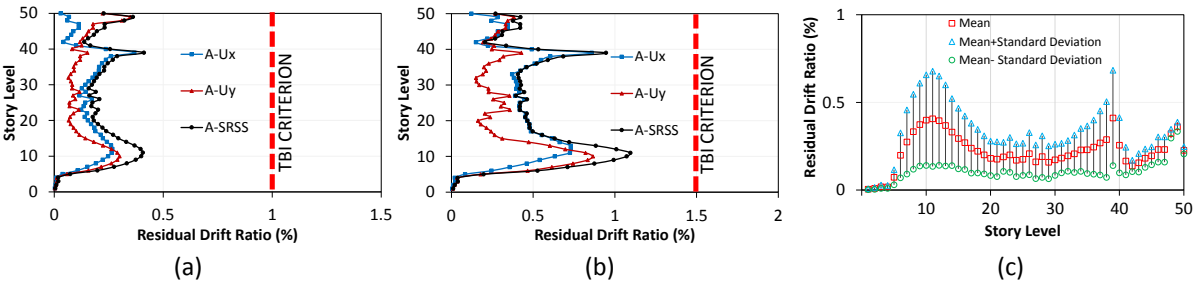

Figure 7 RDRs for 'Apartment Part' (a) Mean-Max RDR histories from different ground motions versus story level (b) Max-Max RDR histories from different ground motions versus story level (c) mean, mean+1SD, and mean-1SD of maximum RDRs

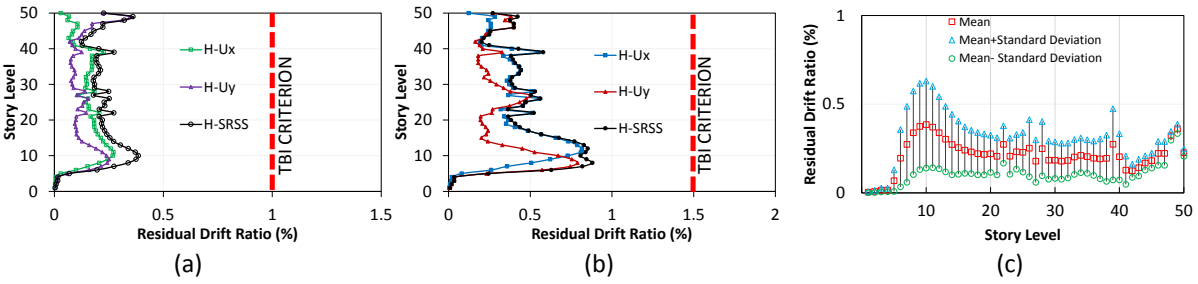

Figure 8 RDRs for 'Hotel Part' (a) Mean-Max RDR histories from different ground motions versus story level (b) Max-Max RDR histories from different ground motions versus story level (c) mean, mean+1SD, and mean-1SD of maximum RDRs

Plastic rotation acceptance criteria

According to the requirements in TBI, ultimate beam plastic hinge rotation for beams in moment frames can be obtained from Chapter 3 of PEER/ATC72. Ultimate beam hinge rotation in the building is determined on the basis of the following equation as stated in Figure 4 (a):

$$\theta_u = 1.5(\theta_p + \theta_y) \tag{5}$$

Beam geometries and material characteristics in the building prove that the ultimate plastic rotation for different beams is around 4%, as a result, this value is accounted as an acceptable criterion. In Figure 9 (a), the heightwise profile of Mean-Max beam end plastic rotations for 'Apartment Part' and Hotel Part' is illustrated. As can be observed end beam rotation almost satisfies TBI acceptance limit along the height. Furthermore, the dispersions of the Mean-Max plastic rotations for apartment and hotel parts of the building are shown in Figure 9 (b), Figure 9 (c), respectively. As can be seen, there is not much scattered results along the height except in the limited number of stories. Additionally, Mean-Max plastic rotations are not necessarily mimic the same heightwise pattern demonstrated for the Mean-max of IDRs or RDRs.

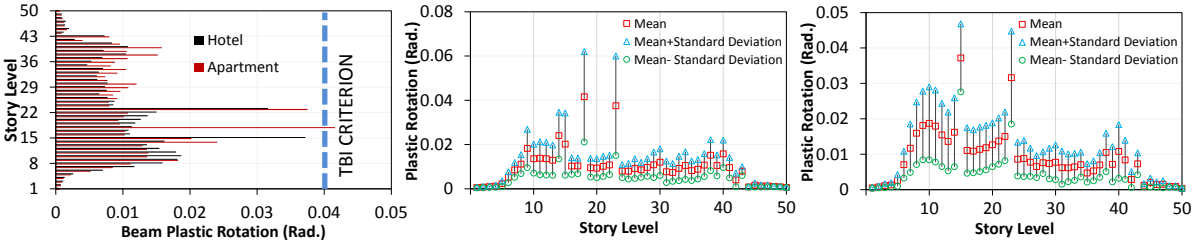

Figure 9 (a) Heightwise distribution of the Mean-Max plastic rotations (b) mean, mean+1SD, and mean-1SD of maximum plastic rotations for 'Apartment Part' (c) mean, mean+1SD, and mean-1SD of maximum plastic rotations for 'Hotel Part'

CONCLUSIONS

In this paper the capability of code-specified requirements, ASCE7-10, for proportioning and detailing of a case study high-rise moment-frame tower to resist against ground motions scaled to MCE hazard level was investigated. Analytical modelling of the structure was simulated based on the recommended parameters in TBI guidelines, Peer/ATC72, and FEMA P440A to incorporate stiffness and strength deterioration in nonlinear history analysis. Acceptance performance criteria corresponding to mean/maximum IDRs, RDRs and end beam plastic rotations were obtained from the recommendations reported in TBI guidelines. The results demonstrated that all the limiting criteria declared by TBI guidelines to provide safety margin against collapse were justifiably satisfied. Dominant modes of response during nonlinear history analyses were governed by p-delta effects and higher mode effects in lower stories and upper stories, respectively. Heightwise profile of plastic hinge rotations at beam ends was rather uniform that indicated spreading of plasticity through different stories.

ABSTRACT

Reinforced concrete (RC) frame-core tube buildings are widely constructed both in China and the United States (US). Their seismic performances greatly influence the economic loss of earthquakes. This study aims to compare the seismic losses of two typical RC frame-core tube tall buildings designed following the Chinese and the US seismic design codes. The prototype building is originally designed using the US seismic design codes, provided by the Tall Building Initiative (TBI) Project. Then the prototype building is redesigned according to the Chinese seismic design codes with the same design conditions and seismic hazard level. Detailed nonlinear finite element (FE) models are established for both designs. These models are used to evaluate their seismic responses at different earthquake intensities, including the service level earthquake (SLE), the design based earthquake (DBE) and the maximum considered earthquake (MCE). In addition, the collapse fragility functions of these two buildings are established using the incremental dynamic analysis (IDA). Subsequently, the seismic loss consequences (repair costs, repair workload, and casualties) of these two designs are calculated using the procedure proposed by FEMA P-58. The comparison shows that the Chinese design exhibits better seismic performances in most cases with smaller total repair cost, shorter repair time and a smaller number of casualties, except slightly longer repair time at the MCE level. For both designs, the repair cost of nonstructural components accounts for the majority of the total cost. The ceilings and elevators are the major causes of casualties at the MCE level.

Frame-core tube, tall buildings, nonlinear analysis, collapse fragility, seismic loss

INTRODUCTION

RC frame-core tube buildings are widely constructed both in China and the US. Their seismic performances greatly influence the economic loss of earthquakes. Comparative studies of the seismic performances of RC frame-core tube tall buildings in China and the US will provide good examples to understand the differences between the Chinese and the US seismic design systems, which may be helpful for further optimization of the design of tall buildings in China. Nonlinear time history analysis (THA) is the most widely used seismic performance assessment method of tall buildings currently. However, the limitations of this method have been identified in terms of: (1) questions regarding the accuracy and reliability of this method in predicting actual building responses; (2) the lack of performance measures that are more meaningful and useful for decision making purposes; (3) the inability to reliably and expediently consider the non-structural systems. The next-generation performance-based seismic design project (FEMA, 2006) developed a new methodology for seismic performance assessment of individual buildings, namely the FEMA P-58 procedure (FEMA, 2012a; FEMA, 2012b), to address these limitations. The technical basis of this methodology is the framework for performance-based earthquake engineering developed by the Pacific Earthquake Engineering Research Center (PEER) (Moehle and Deierlein, 2004). The FEMA P-58 procedure accounts for the uncertainties associated with current ability to accurately predict the actual response, the intensity of ground shaking, the actual occurrence of the damage state, etc. This procedure uses a probabilistic approach to characterize performance so that the reliability with which performance may be attained can be fully understood. Unlike the nonlinear THA, which describes the building performance in terms of structural responses such as story drift ratio, acceleration and material stress, the FEMA P-58 procedure describes the structural performance in terms of the consequences of earthquake damage including: casualties; repair costs, repair time, etc.

This study aims to compare the seismic losses of two typical RC frame-core tube tall buildings designed following the Chinese and the US seismic design codes. The prototype building is originally designed using the US seismic design codes, provided by the TBI Project (Moehle et al., 2011). Then the prototype building is redesigned according to the Chinese seismic design codes with the same design conditions and seismic hazard level (Lu et al., 2015). Detailed nonlinear FE models are established for both designs. These models are used to

evaluate their seismic responses at different earthquake intensities. In addition, the collapse fragility functions of these two buildings are established using the IDA. Based on the above analysis, the seismic loss consequences (repair costs, repair workload and casualties) of these two designs are calculated using the procedure proposed by FEMA P-58.

DESCRIPTION OF THE STUDIED BUILDINGS

The prototype RC frame-core tube building, Building 2A, is one of the case study buildings in the TBI research program launched by PEER in 2006 (Moehle et al., 2011). Building 2A is a 42-story residential building including a 6.1-m tall penthouse on the top. The total height of the building is 141.8 m above the ground. Figure 1(a) shows the three-dimensional (3D) view and the typical floor plan of this building. Building 2A was designed based on the International Building Code (ICC, 2006). The published report of Moehle et al. (2011) provided detailed design information and outcomes of Building 2A.

Building 2A is redesigned following the Chinese codes by the authors, mainly including the Code for the Seismic Design of Buildings GB50011-2010 (CMC, 2010a), the Technical Specification for Concrete Structures of Tall Building JGJ3-2010 (CMC, 2010b), and the Code for Design of Concrete Structures GB50010-2010 (CMC, 2010c). The redesigned building is referred to as Building 2N. All design details of Building 2N, including the structural configuration and dimensions, the vertical design loads, the site conditions and the seismic hazard level, are identical to those for Building 2A. A detailed comparison of the two designs can be found in Lu et al. (2015). Lu et al. (2015) indicates that Building 2N has larger columns and more internal walls in the core tube. The seismic design forces determined by the Chinese response spectrum are larger than the US counterparts at the same seismic hazard level. In addition, a higher requirement for the story drift ratio is specified by the Chinese codes, thereby resulting in larger seismic design forces. These two aspects together have led to a higher level of material consumption (concrete and reinforcement) for Building 2N than Building 2A.

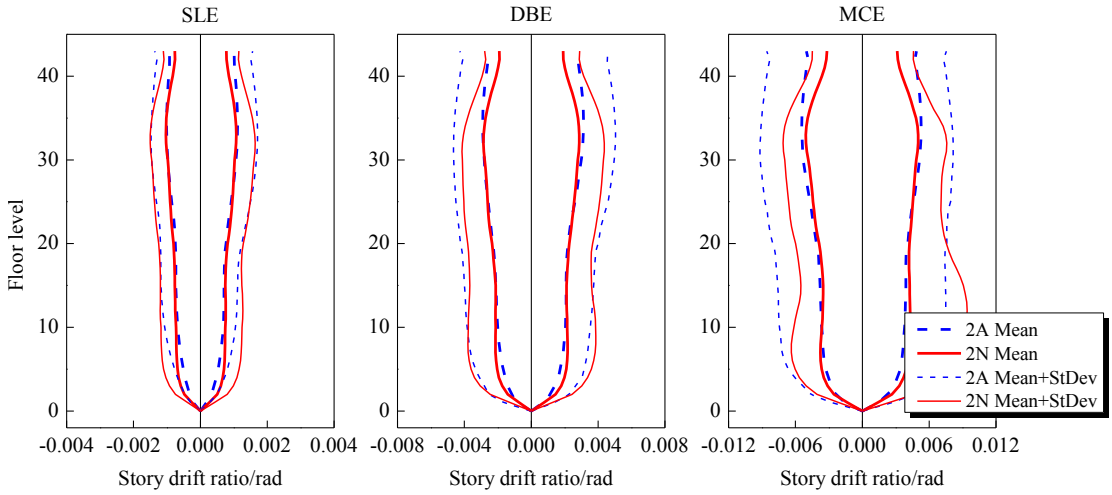
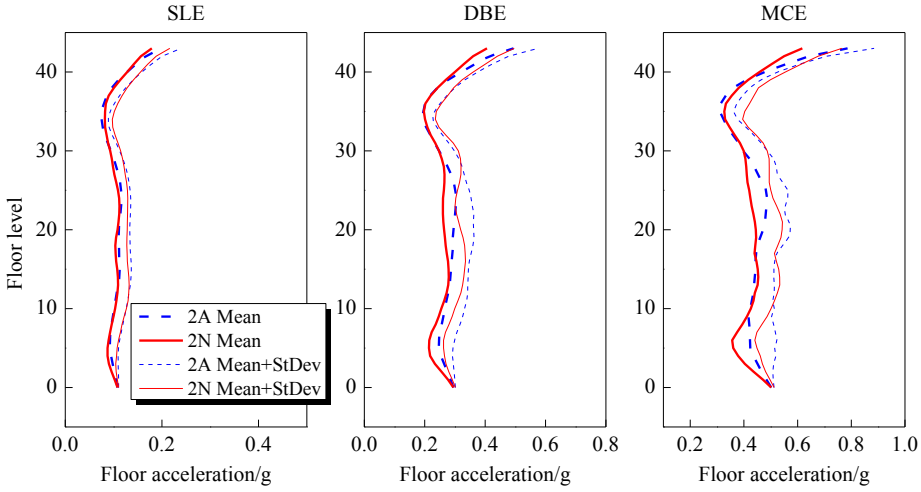
Figure 1 Three dimensional views and typical floor plans of Buildings 2A and 2N (unit: mm)

NONLINEAR FE ANALYSIS OF BUILDINGS 2A AND 2N

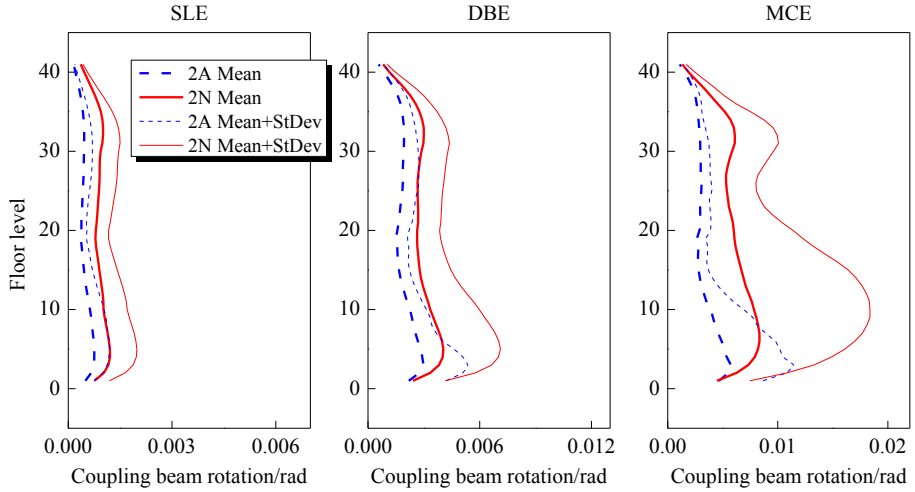
Based on the design outcomes of Buildings 2A and 2N, 3D nonlinear FE models of the two buildings are established using MSC.Marc software. Modeling details can be found in Lu et al. (2015). The nonlinear THA is intended to assess and compare the performances of Buildings 2A and 2N for different earthquake intensities. To achieve this object, three earthquake intensities are selected, including SLE (i.e. a 63% probability of exceedance in 50 years), DBE (i.e. a 10% probability of exceedance in 50 years) and MCE (i.e. a 2-3% probability of exceedance in 50 years) in the Chinese code. The popularly used 22 records of far-field ground motions recommended by FEMA P695 (FEMA, 2009) are adopted in the following structural seismic evaluation. The corresponding peak ground acceleration (PGA) values of these selected ground motion records are scaled to 110, 300 and 510 cm/s^2 for SLE, DBE and MCE, respectively, which is specified in the Chinese seismic design code GB 50011-2010 (CMC, 2010a) for the intensity 8.5 region. The scaled ground motion records are input along the X direction of the buildings, and the classical Rayleigh damping is adopted with a damping ratio of 5% for the nonlinear THA.



(a) Story drift ratio



(b) Floor acceleration



(c) Coupling beam rotation

Figure 2 Structural responses of Buildings 2A and 2N

The mean values and standard deviations of story drift ratio, floor acceleration and coupling beam rotation of Buildings 2A and 2N subjected to the selected ground motion records are shown in Figure 2. Figure 2(a) indicates that both the negative and positive mean story drift ratios of the two buildings are very similar for all the three earthquake intensities, while the maximum story drift ratio of Building 2A is slightly larger than that of Building 2N. Figure 2(b) demonstrates that the mean acceleration responses of Building 2A are also larger than that of Building 2N at most floors. In addition, the maximum acceleration response occurs at the top floor in both buildings. Figure 2(c) shows that the coupling beam rotations are obvious greater for Building 2N, as the

coupling beams in Building 2N have larger span-depth ratio than those in Building 2A (Lu et al., 2015).

IDA (Vamvatsikos and Cornell, 2002) is an effective method to evaluate the seismic performance of structures. Therefore, IDA is performed to evaluate the collapse resistance capacities of Buildings 2A and 2N. The ground motion intensity is increased gradually in IDA until the collapse occurs. Then, the critical ground motion intensity resulting in the structural collapse is obtained and the collapse fragility curves of these two buildings are shown in Figure 3. It indicates that Building 2N has a slightly higher collapse resistance capacity than that of Building 2A.

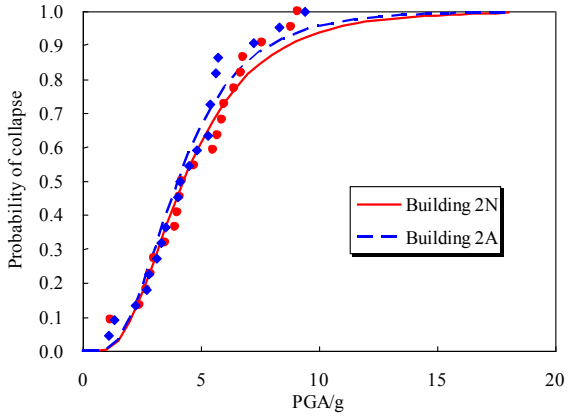


Figure 3 Collapse fragility functions of Buildings 2A and 2N

BUILDING PERFORMANCE MODELS OF PACT

The key step of the FEMA P-58 assessment procedure is to develop the building performance model. The performance model is a categorization of all those structural and nonstructural building components that are vulnerable to earthquake induced damage (Hamburger, 2011). In addition, the occupancy and the distribution of people in the building also need to be defined in the performance model. Vulnerable building components are categorized into fragility groups and performance groups. Fragility groups are sets of similar components that have the same potential damage characteristics in terms of vulnerability and consequences. Performance groups are subsets of a fragility group that will experience the same earthquake demands in response to earthquake shaking (FEMA, 2012a). Each fragility group has an associated series of damage states. Each damage state leads to a unique set of potential consequences, which may require some repair actions or threaten human life. The type and extent of damage that a component will experience is determined by using fragility functions. The component fragility functions are the distributions that indicate the conditional probability of incurring a damage state given a value of demand (FEMA, 2012a). Each damage state for each performance group also has an associated consequence function. Consequence functions are relationships that indicate the potential distribution of losses as a function of damage state. Consequence functions translate damage into potential repair and replacement costs, repair time, casualties, and other impacts (FEMA, 2012a).

Over 700 fragilities for common structural and nonstructural components and contents found in typical buildings and occupancies have been developed and provided as part of the FEMA P-58 methodology (FEMA, 2012b), called "Fragility Specification". Fragility specifications include information on component damage states, fragility functions, and consequence functions. For practical implementation of this methodology, an software, referred to as the Performance Assessment Calculation Tool (PACT) were developed, to help assemble the building performance model and implement a large number of building performance calculation.

This section briefly describes the PACT building performance models of Buildings 2A and 2N. Moehle et al. (2011) provides the total replacement cost of Building 2A ($149 million) and Davis Langdon Company (2010) presents the details of this cost. As Buildings 2A and 2N have the identical architectural layout and occupancy, this study assumes that all the other expenses for Building 2N are the same as Building 2A, except for the cost resulted from different amount of structural material consumptions (Lu et al., 2015). Accordingly, the total replacement cost of Building 2N is estimated as $151.3 million. The provided consequence functions in PACT represent the repair costs appropriate to Northern California in 2011. Users can address escalation and regional cost variation through the Region Cost Multiplier and Date Cost Multiplier to adjust the provided component repair cost consequence functions to appropriate present values (FEMA, 2012b). Since this study focuses on the differences of the seismic losses between the Chinese and the US designs, the inflation and region effect are ignored and the Region Cost Multiplier and Date Cost Multiplier are both assumed to be 1.0. The total loss threshold, which is the percentage of the construction cost where the structure would be taken as irreparable, is

assumed to be 1.0. A value of 1.0 insures that all the true consequence data is presented. If the value is less than 1.0, the consequences for realizations with higher costs would be replaced with the total repair costs and time, and the actual results would be lost (Jarrett et al., 2015). The replacement time for the two buildings is taken as 1500 days estimated in accordance with Comerio and Blecher (2010) and Comerio (2000). The occupancy type of the two buildings is retailing for the first floor and residence for all the other floors (Moehle et al., 2011). The corresponding population model provided by the PACT program is used.

Table 1 Structural component fragility specifications used in PACT models

Structural component name	Fragility specification	
	Building 2A	Building 2N
Moment frame joint	B1041.002a, B1041.003b	B1041.001a, B1041.001b B1041.002a, B1041.002b

	Low voltage switchgear	D5012.021a
	Distribution panel	D5012.031a
Equipment and furnishings		Not considered

Following the definition of the general building characteristics, it is necessary to define the quantity, vulnerability, and distribution of damageable components and contents. PACT organizes this process into two parts: (1) identification of required fragility specifications for each floor, and (2) further division of fragility

specifications into different performance groups according to their demand parameters, and identification of the quantity of components in each performance group at each floor (FEMA, 2012b). The structural fragilities used in this study are shown in Table 1. The quantity of each structural performance group is calculated based on the actual number of structural components. The nonstructural component fragilities are chosen based on the building occupancy type with the aid of the provided Normative Quantity Spreadsheet, a supplemental file provided by the FEMA P-58 products. Table 2 shows the nonstructural fragilities used, which is identical for both the two buildings.

Depending on the selected fragility specifications, the peak story drift ratio, peak floor acceleration and peak coupling beam rotation are used as the structural demand parameters, which need to be entered into PACT. The previous THA of Buildings 2A and 2N has obtained these demand parameters for the selected 22 ground motions. The collapse fragility functions of these two buildings (Figure 3) are also established. When collapse occurs, the mean fatality rate, which is the fraction of occupants inhabiting the impacted collapse area who are fatally injured by the collapse, is assumed to be 10%; and the mean injury rate is assumed to be 90% according to FEMA (2008). One thousand Monte Carlo realizations are performed, which is generally sufficient to produce stable loss results (FEMA, 2012b).

SEISMIC LOSS RESULTS

With the parameters mentioned above, the seismic losses of Buildings 2A and 2N subjected to three different earthquake intensities are assessed using the FEMA P-58 procedure. No collapse has occurred in all 1000 realizations and the detailed assessment results are discussed as follows.

Repair cost

The median repair costs of Buildings 2A and 2N at three different earthquake intensities are compared in Figure 4. Since the comparison is conducted based on the median values, the median total repair cost does not equal to the sum of median structural and non-structural components repair costs. Figure 4 indicates that, in both designs, the repair cost of non-structural components accounts for the majority of the total repair cost at all the three earthquake intensities. At the SLE and DBE levels, the repair cost of structural components is very small; while this value increases at the MCE level.

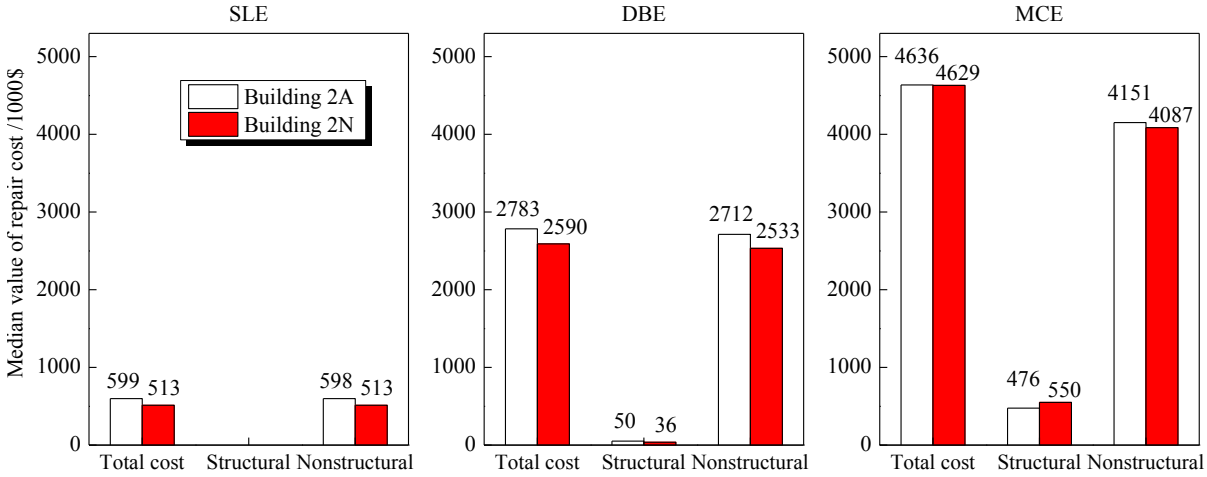

Figure 4 Median values of the repair cost for Buildings 2A and 2N

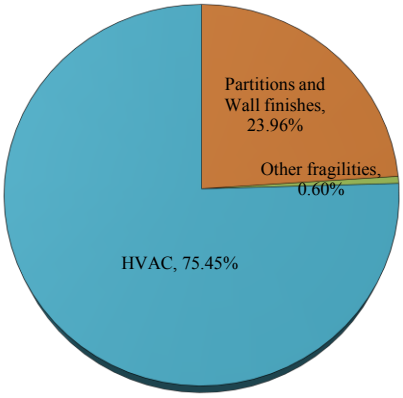
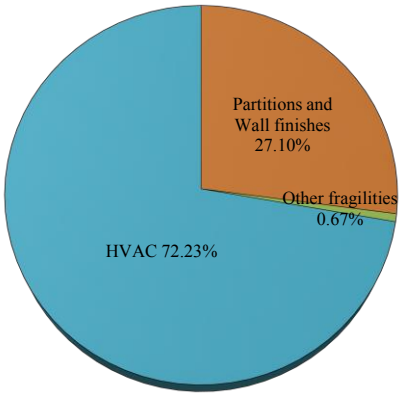
Comparison between the two buildings demonstrates that the median total repair cost of Building 2A is larger than that of Building 2N at all earthquake intensities. At the SLE and DBE levels, the total repair cost is dominated by the non-structural components, so the smaller non-structural component repair cost of Building 2N leads to an obviously smaller total cost. At the MCE level, the damage of structural components increase and Building 2N has more structural components (more internal walls, coupling beams and frame beams). These two reasons lead to a larger structural component repair cost in Building 2N than that that in Building 2A. Although Building 2N still has an obviously smaller repair cost of non-structural components, the gap between the total costs of Buildings 2A and 2N has been narrowed.

Note that the repair costs of Building 2A also has been assessed in the TBI program with the FEMA P-58 procedure (Moehle et al., 2011). Because the ground motions selected in the TBI program are different from

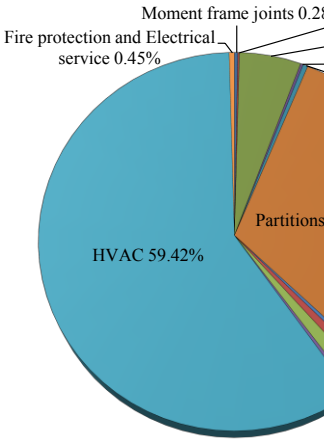
those used in this study, the corresponding response demand parameters and the estimated repair costs are consequently not consistent with each other. Additional verification indicates that if the structural responses used in the TBI program are also adopted in this assessment, the calculated repair costs will coincide with the values in the TBI program. It proves that the established building performance models and the operational approach used in this study are correct.



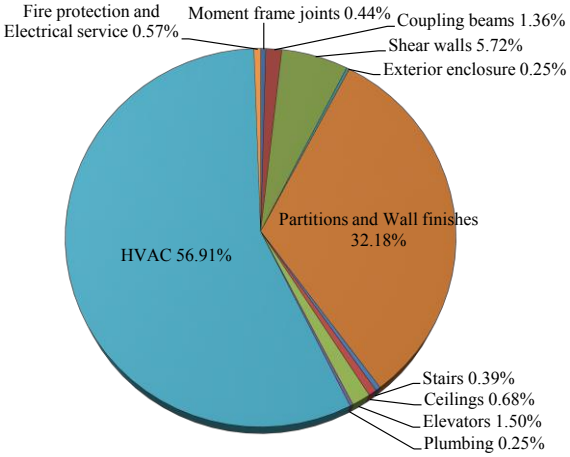
(a) Building 2A decomposition at the SLE level



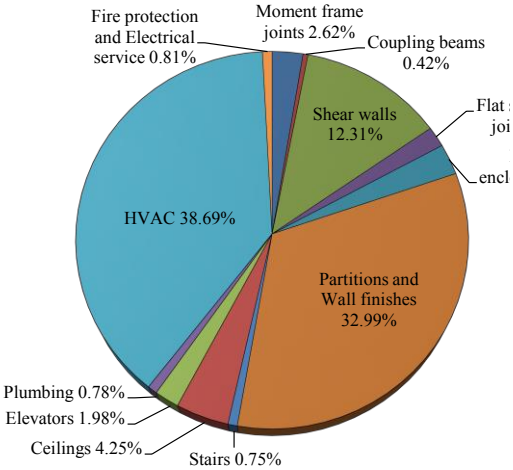
(b) Building 2N decomposition at the SLE level



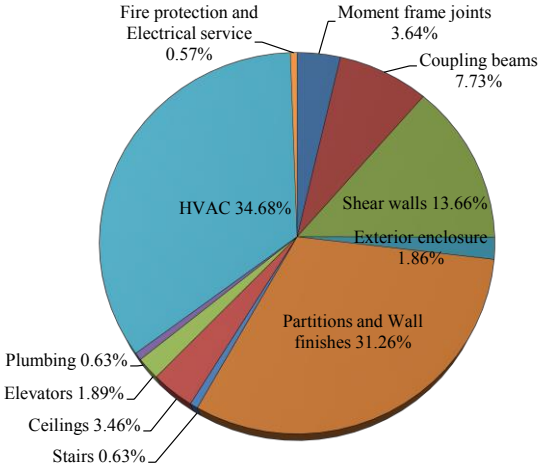
(c) Building 2A decomposition at the DBE level



(d) Building 2N decomposition at the DBE level



(e) Building 2A decomposition at the MCE level



(f) Building 2N decomposition at the MCE level

Figure 5 Decomposition of the total repair costs for Buildings 2A and 2N

The decomposition of the total repair costs for Buildings 2A and 2N are shown in Figure 5. Figures 5(a) and 5(b) reveal that the repair costs are mainly caused by the damage of HVAC system, partitions and wall finishes at the SLE level. And at the DBE level (Figures 5(c) and 5(d)), the repair costs of HVAC system, partitions and wall finishes still account for the majority of the total cost. Meanwhile, the damage of shear walls, coupling beams, ceilings and elevators cannot be neglected either. At the MCE level (Figure 5(e) and 5(f)), the repair cost of structural components increases obviously, in which the repair cost of shear walls accounts for the majority.

Repair time

The repair time is characterized by the number of work days required for building restoration. A work day represents the labor quantity of a worker in one day. The comparison of the median values of the repair work days for Buildings 2A and 2N are shown in Figure 6. Similar to the repair cost, the median repair workload of nonstructural components accounts for the majority of the total repair workload for both designs at all the three earthquake intensities. The median repair workload of structural components is very small at the SLE and DBE level; while at the MCE level, this value becomes larger.

Comparison between the two buildings demonstrates that Building 2A has a larger amount of workload than that of Building 2N at the SLE and DBE levels. However, Building 2N requires a larger amount of workload at the MCE level. Three main reasons contribute to this conclusion: the damages of structural components increase at this level, Building 2N has more structural components, and the repair times for structural components are generally longer than those of non-structural components.

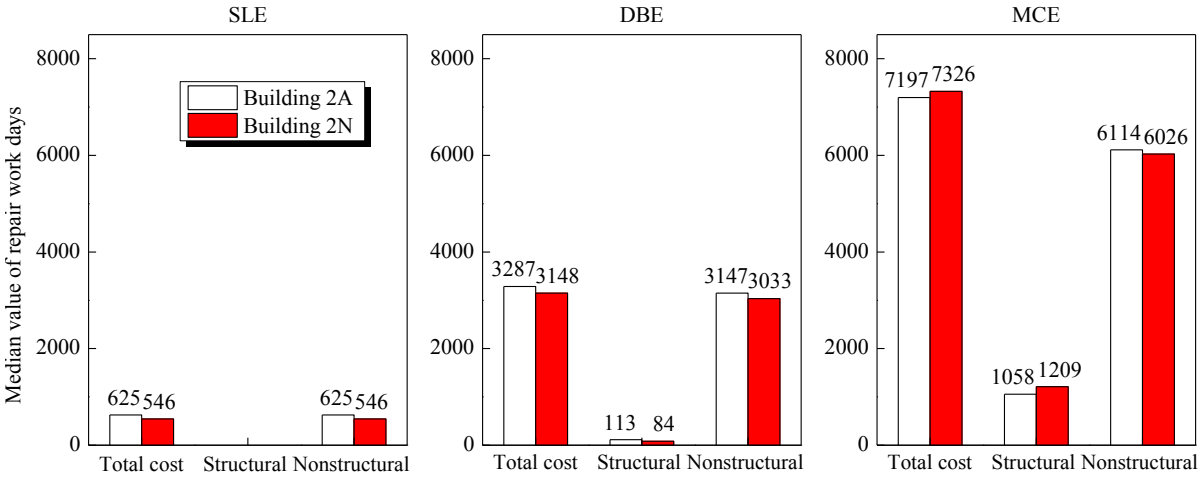


Figure 6 Median values of the repair work days for Buildings 2A and 2N

Casualties

No casualties occur for both buildings at the SLE and DBE levels. Table 3 shows the casualties of Buildings 2A and 2N at the MCE level. The overall casualties are quite low and Building 2N has a relatively smaller number of casualties. The ceilings and elevators are the major causes of casualties at the MCE level. Thus, credible measures ensuring the anchor of ceilings and other fragile non-structural components and the safety of the elevators can effectively reduce the direct casualties caused by earthquakes.

Table 3 Casualties of Buildings 2A and 2N at the MCE level

	Building 2A		Building 2N	
	Median value	Ninety percent value	Median value	Ninety percent value
Number of injuries	0.0577	0.447	0.0285	0.418
Number of fatalities	0.00157	0.0253	0.00166	0.0249

CONCLUSIONS

This study provides the comparative analyses of the seismic losses of two typical RC frame-core tube tall buildings designed following the Chinese and the US seismic design codes. The FEMA P-58 procedure is used to assess the seismic loss consequences. The comparison shows that the Chinese design exhibits better seismic performances in most cases with smaller total repair cost, shorter repair time and a smaller number of casualties, except slightly larger repair time at the MCE level. For both designs, the repair cost of nonstructural components accounts for the majority of the total loss. The ceilings and elevators are the major causes of casualties at the MCE level.

ABSTRACT

This paper presents how performance-based design (PBD) approaches can help to improve the structural performance and cost effectiveness in design of floor diaphragms of tall buildings under earthquakes. In contrast to the prescriptive design approaches, performance-based design provides a systematic methodology for assessing the performance capability of overall building system and its components. The performance-based design explicitly evaluates the response of the building under the potential seismic hazard, considering the probable site-specific seismic demands as well as the uncertainties in the post-yielding response and behaviour of the building under seismic events. Case study of 57-story reinforced concrete residential building with 4 basement levels is presented. The building was designed for Design Basis Earthquake (DBE) level in accordance with traditional code-based design procedures at the preliminary design stage. After preliminary design, the performance of the building was checked explicitly at Service Level Earthquake (SLE) (43-year return period) and Maximum Considered Earthquake (MCE) level (2475-year return period), using linear and nonlinear response history procedures. Diaphragm design forces at podium level and tower levels were explicitly checked at site-specific MCE level event rather than application of code-specified modification factors to estimate the forces and deformation under code-specified earthquake level. Cost effectiveness of the design was evaluated by comparison of the indicative quantities and parameters between the code-based design and the modified design based on PBD.

KEYWORDS

Performance-based design, diaphragm, tall building, earthquake.

INTRODUCTION

Performance-based design is a state-of-the-art design approach for the seismic-resistant design, which has been widely used, for seismic evaluation of existing buildings and seismic design of number of new tall buildings. The conventional seismic design codes consider the reduction in design seismic force which implies the structural inelastic behaviour through the application of seismic response modification factor, R, in the simplified elastic analysis methods. While allowing inelastic deformation in the deformation-controlled members detailed for ductility, force-controlled members that are designed to remain elastic would experience the significant higher seismic force demand than reduced design forces by seismic response modification factor. To account for this effect, structural overstrength factor, Ω_0, is multiplied to the design seismic forces to predict the maximum forces in members that are to remain elastic, especially in design of diaphragms. The intent of those factors is to simplify the structural design process by application of elastic analysis procedures. Those procedures do not consider the structural performance of component level, the ground motion characteristics and redistribution of seismic demand in the various components of building at the state of inelastic behaviour under strong seismic events.

In contrast to the prescriptive design approaches, performance-based design provides a systematic methodology for assessing the performance capability of a building, system or component. The performance-based design explicitly evaluates the response of the building under the potential seismic hazard, considering the different probable site-specific seismic demand levels as well as the uncertainties in the post-yielding response and behaviour of the building.

The case study building is a high-rise residential tower, which is 57-story high-rise building, approximately 192 meters from ground level to lower roof deck level. The building is the second tower of two-tower residential development project, sharing a common podium with 4-story below-grade parking. The seismic force-resisting

system is a bearing wall system, comprised of special reinforced concrete shear walls. Post-tensioned flat slab is used in the floor system of towers while beam and slab system is used in the podium levels.

OVERALL METHODOLOGY

The overall methodology performance-based design followed "Tall Buildings Initiative, Guidelines for Performance Based Seismic Design of Tall Buildings, 2010" developed by Pacific Earthquake Engineering Research Center.

Initially, a schematic design was carried out to achieve the good performance and cost effectiveness of the structural system. Following the schematic design, the preliminary design was carried out in accordance with conventional building code procedure, ASCE/SEI 7-05 and ACI 318-08, applying the seismic loading of Design Basis Earthquake (DBE) level and wind loading, to determine the size of the members and reinforcement.

After substantial completion of code-based design, performance-based evaluation was carried out to check the performance at two levels of earthquakes; Service/Frequent Earthquakes (SLE) and Maximum Considered Earthquakes (MCE). The design was revised as appropriate, based on the performance-based evaluation results and findings in order to meet the seismic performance objectives and acceptance criteria set for the project. Probabilistic site-specific seismic hazard assessment was carried out to determine the seismic hazard of the project site, considering all possible earthquake occurrences and ground shakings to determine a combined probability of exceedence that incorporates the relative frequencies of occurrence of different earthquakes and ground-motion characteristics. Seven pairs of ground motion records were selected and scaled spectrally for MCE level evaluation.

Modelling and Analysis Procedures

Complete, three-dimensional elastic computer models including the tower and the entire podium were analysed using ETABS. The elastic models were used for wind, SLE and DBE level earthquake analysis. The models included the shear walls, columns, coupling beams, girders, beams, slabs, and foundation. Shell elements were used to model the floor slabs, considering the diaphragm flexibility. Soil springs were applied to the mat foundation.

Non-linear verification model was created in Perform-3D for MCE level evaluation. Tower and the entire podium were modelled in nonlinear model. Equivalent "slab-beams" were used in the model in order to determine the nonlinear response of post-tensioned slab, interaction with shear walls and columns. Floor mass was lumped at centre of mass location and rigid diaphragm assumption was applied in the tower floors. The model included inelastic member properties for elements that were anticipated to be loaded beyond their elastic limits. These include the flexural response of shear walls, coupling beams and slab-outrigger beams. Elements that were assumed to remain elastic were modelled with elastic member properties. In order to account the soil-structure interaction, a rigid "bathtub" modelling approach was used to model the basement wall. Nonlinear elastic bar elements were connected between the rigid bathtub and basement wall.

Response spectrum analysis was conducted to check the performance under SLE level earthquakes while nonlinear response history analysis (NLRHA) was conducted to check the performance under MCE level earthquakes.

SEISMIC PERFORMANCE OBJECTIVES

The specific performance objectives for the design of the building at two levels of earthquake hazards are shown in the Table 1.

Table 1 Seismic performance objectives

Level of Earthquake	Seismic Performance Objective
Frequent/Service: 50% probability of exceedance in 30 years (43-year return period), 2.5% of structural damping	Serviceability: Limited structural damage, should not affect the ability of the structure to survive future Maximum Considered Earthquake shaking even if not repaired.
Maximum Considered Earthquake (MCE): 2% probability of exceedance in 50 years (2475-year return period), 2 to 3% of structural damping	Collapse Prevention: Building may be on the verge of partial or total collapse, extensive structural damage; repairs are required and may not be economically feasible.

OVERALL ANALYSIS RESULTS

In modal analysis, the first two modes are translation in Y and X directions respectively while the third mode is in torsion. Figure 2 compares the elastic base shear percentage of SLE, DBE, MCE and inelastic base shear of MCE (average base shear of NLRHA), in terms of weight of building above 3rd floor level of tower. Nonlinear base shear at MCE level is approximately 0.5 and 0.4 times less than the elastic base shear in X and Y directions respectively.

Table 2 Natural periods of the building

Mode	Period (s)	Modal Mass Participation Ratio	
		X (%)	Y (%)
1	7.39	7.44	39.74
2	5.35	38.91	8.17
3	4.23	0	0

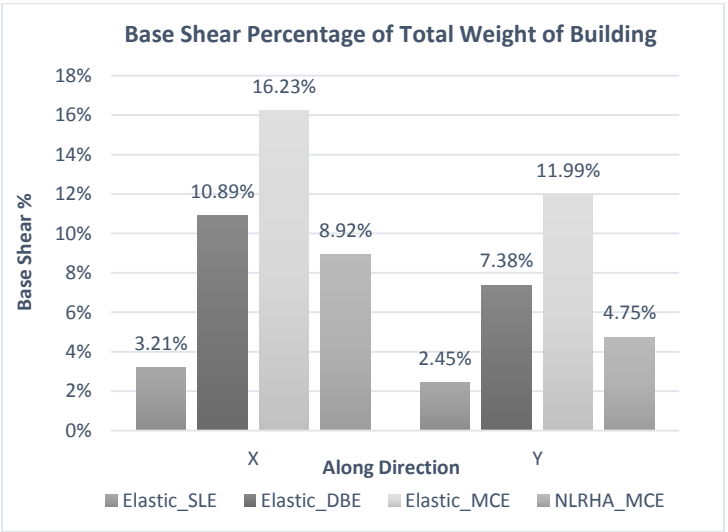

Figure 2 Base shear comparison (Weight of building = 1,040,200 kN)

DIAPHRAGM DESIGN

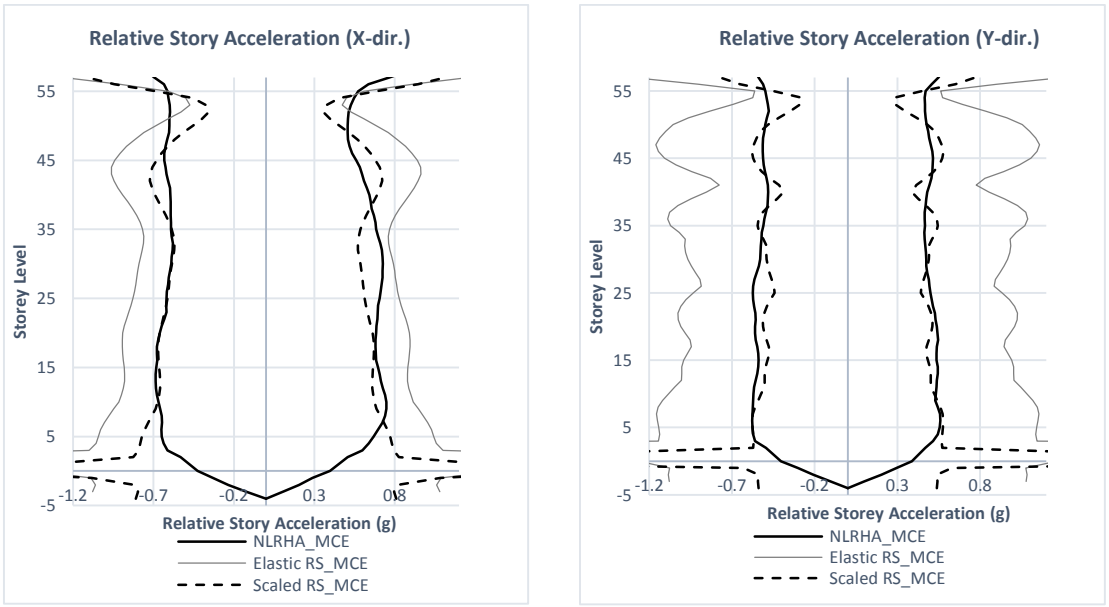
In seismic design of buildings, diaphragms transfer in-plane forces, comprising of inertial forces and transfer forces to vertical members of seismic forces-resisting system. Inertial forces are generated from the mass of the floor system under ground shaking. Transfer forces are in-plane forces, transferred from one vertical element of

seismic force-resisting system to another. Transfer forces are significant at discontinuities in the vertical elements commonly lateral force transfer between shear walls in tower and basement walls and lateral force transfer between multiple towers, through the podium slab.

Generally, in code-specified procedures, diaphragms are designed for the maximum of design seismic force from structural analysis of seismic force-resisting system and diaphragm design force, which is determined based on acceleration times mass. Since the overall design philosophy provides essentially elastic diaphragm, diaphragm components, such as collectors, distributors, and diaphragm slab are designed, multiplying the design forces with structural overstrength factor, Ω_0. The structural overstrength factor varies approximately 2 to 3, depending on the seismic force-resisting system.

Tower Diaphragm

In case study building, story accelerations from nonlinear response history analysis under MCE level earthquakes were used to determine the diaphragm design forces. Since equivalent slab-beams and rigid diaphragm assumption were used in the nonlinear verification model at MCE level, diaphragm design forces could not be extracted directly from the nonlinear model. Diaphragm design forces were checked from ETABS model in which the slabs were modelled with shell elements. Response spectrum analysis was conducted in ETABS, using MCE level response spectrum. The appropriate scale factors for response spectrum analysis was determined, by scaling between average story acceleration from nonlinear response history analysis and response spectrum analysis since the inertial forces were governing the design rather than transfer forces in the tower diaphragms. The scale factor of 0.75 and 0.5 were used to scale the elastic forces from response spectrum analysis at MCE level. Figure 3 presents the scaling of story acceleration at MCE level in response spectrum analysis.



(a) (b)

Figure 3 Scaling of story acceleration in response spectrum analysis at MCE level: (a) X-direction, (b) Y-direction

As diaphragm was idealized with finite element model, diaphragm was designed according to stress fields from analysis and non-uniform shear flow was taken into account. Section cuts were assigned to determine the design forces of diaphragm components based on the stress fields. Diaphragm components were designed for forces from section cuts, without amplification with structural overstrength factor, Ω_0. Factor of 1.5 was used to account for uncertainty in the maximum mean force demand in ground motions. Diaphragm strength was calculated in accordance with ACI 318-08, using expected material properties and code-specified strength reduction factors.

The diaphragm design was compared between code-specified procedure and performance-based procedure. In code-based procedure, DBE level response spectrum analysis results were scaled down to estimate the inelastic demand forces, using seismic response modification factor, R, in accordance with code-specified procedures.

The diaphragm forces were multiplied with structural overstrength factor of 2.5 and redundancy factor of 1.0 to determine the diaphragm design forces. In both response spectrum cases at DBE and MCE levels, orthogonal effects were considered in design, applying 100% of seismic forces in one principal direction combined with 30% of seismic forces in the orthogonal direction. Figure 4 verifies the diaphragm load path with the inertial force of the diaphragm at Level 20, from MCE level response spectrum analysis in Y-direction. Orthogonal effects and load factor of 1.5 was not considered in the load path verification.

Diaphragm design forces and the required reinforcement in collector and shear friction transfer in sample locations at Level 20 were compared between performance-based design at MCE level and code-based design at DBE level. Figure 5 presents the sample locations of section cut for collector and shear friction transfer at Level 20. It was found that performance-based design provides more reliable and cost-effective design, considering more realistic responses under seismic events.

Performance-based	MCE	608	4-DB25	1045	DB12@175 mm

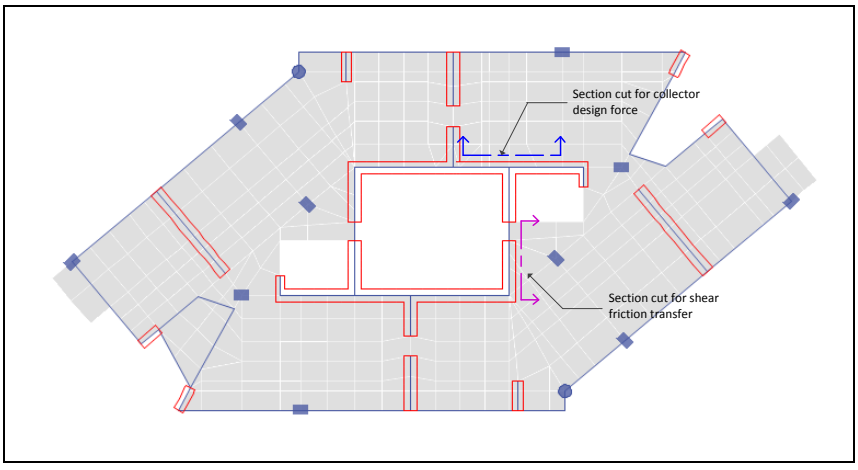

Figure 5 Section cut for collector and shear friction transfer at sample locations

Podium Diaphragm

For diaphragm design at ground and basement levels, combined complete two-tower ETABS model was used to check the transfer forces in diaphragm. MCE level response spectrum analysis results were scaled to average

nonlinear base shear since the transfer forces from towers were governing the design. Also, simplified ETABS model was created with two towers up to 2nd floor and apply the forces equivalent to the MCE average nonlinear base shear of each tower at 2nd floor with different scenarios to consider the in-phase and out-phase effects. Linear static analysis was conducted for the simplified model. Diaphragm shear, tension and compression between two towers were checked based on the results from complete two-tower model and simplified model.

CONCLUSIONS

Performance-based design approaches explicitly check the global and component responses of the building against the detailed acceptance criteria for multiple seismic events rather than application of modification factors to estimate the forces and deformation under single code specified seismic demand level. PBD approaches capture the more reliable behaviour of diaphragms in seismic design which can lead the better structural performance and cost effective design.

ABSTRACT

Glass or carbon fibre reinforced polymers are extensively used in the automobile and the aerospace industries. However, in civil infrastructure their usage is mainly limited to retrofitting, because synthetic fibres are expensive. Steel is heavy, expensive and subject to corrosion. Instead of steel reinforcement in civil structures the usage of natural materials will reduce the total mass and cost of the structures and circumvent the long-term problem of corrosion. In this paper flax fibre reinforced polymer (FFRP) and coconut fibre reinforced concrete (CFRC) are investigated. Because of the usage of less mass the corrosion-free composite structures will experience less effect of dynamic loads and require less running maintenance. The seismic performance of a simple bridge pier made of FFRP-CFRC composite is presented. The earthquake loading is simulated by a shake table. The results indicate that the new composite has a potential for becoming resilient construction materials for future structures.

KEYWORDS

Natural fibre, seismic performance, polymer-concrete composite, fibre reinforcement, bridge pier.

INTRODUCTION

A composite is when two or more different materials are combined together to create a superior and unique material. In the last decades fibre reinforced polymer (FRP) composite materials have been widely investigated. In recent years more and more FRP is used in concrete structures. Man-made fibres, such as glass, carbon, and aramid fibres have been used as the main FRP materials. Synthetic materials now have been developed to a certain level and dominate the aerospace, automotive, construction industries, because of their high stiffness and corrosion resistance performance. It has been replacing metal as the new material of choice. The main motivation of using FRP composite is the long-term issue of steel. It is only a question of time that corrosion will occur that will significantly affect the integrity of the structures. For example, bridge structures made of conventional construction materials, steel or concrete with steel reinforcement, especially in coastal regions deteriorate with the time due to corrosion of steel. Figure 1 shows one example of a degradation of bridge decks observed in 2010 in Toronto, Canada.

Because of the increasing environmental concern, construction industries are keen on developing sustainable construction materials. One significant step to achieve a sustainable concrete industry is the use of natural materials as reinforcement of concrete and FRP composites, such as natural fibres to replace synthetic glass or carbon fibres. The usage of non-corrosive materials, e.g. glass or carbon fibre reinforced polymer (G/CFRP), in civil infrastructure is very limited because of the high initial cost. To overcome the high cost natural materials can be utilized without compromising the strength of the composite material and thus lead to construction materials for structures in the future (Yan and Chouw, 2012a, 2012b). Raftery and Kelly (2015) proposed the usage of basalt fibre reinforced polymer for strengthening timber structures. Cheah (2014) investigated the usage of flax fibre in traditional earth houses in Maori communities in New Zealand. Ali *et al*. (2009, 2012, 2013a, 2013b) proposed the usage of coconut fibre reinforced concrete for low-cost earthquake-resistant low-damage structures, especially in earthquake regions of developing countries. The low-damage structures are achieved by letting each structural member to move relative to each other. Whenever the earthquake loading exceeds a threshold, each structural member performs rigid body movements. Since rigid body movements do not cause deformation of the structural members, no stress will develop and thus no damage to the structure will be anticipated.

Figure 1 Damage to bridge structures observed in 2010 in Toronto, Canada, due to corrosion of steel reinforcement

NATURAL FIBRE REINFORCED POLYMER-CONCRETE STRUCTURES

This research focuses on engineering design of new composite structural members and assembled structures. In comparison with steel reinforcement, commonly used in conventional constructions of civil infrastructure, FFRP-CFRC composite structures are not only corrosion free, the structures are also much lighter. Consequently, the impact of dynamic loadings, e.g. due to heavy vehicles, high-speed train, wind or earthquake, will be reduced because less inertia forces will be activated due to less mass involvement. To further reduce the mass of the structure, double FFRP tube confined CFRC core is investigated. The inner and outer FFRP tubes serve as inner and outer permanent formwork, respectively. While the behaviour of double skin steel tube confined concrete structural members has been investigated extensively (e.g. Tao and Han, 2004 and 2006, Wright *et al*. 1991a and 1991b, Lu and Kennedy, 1993), the performance of double flax fibre reinforced polymer confined coconut fibre reinforced concrete (DFFRP-CFRC) composite is unknown. To the authors' knowledge the behaviour of DFFRP-CFRC composite is studied for the first time in this work. Figure 2 shows the two configurations considered.

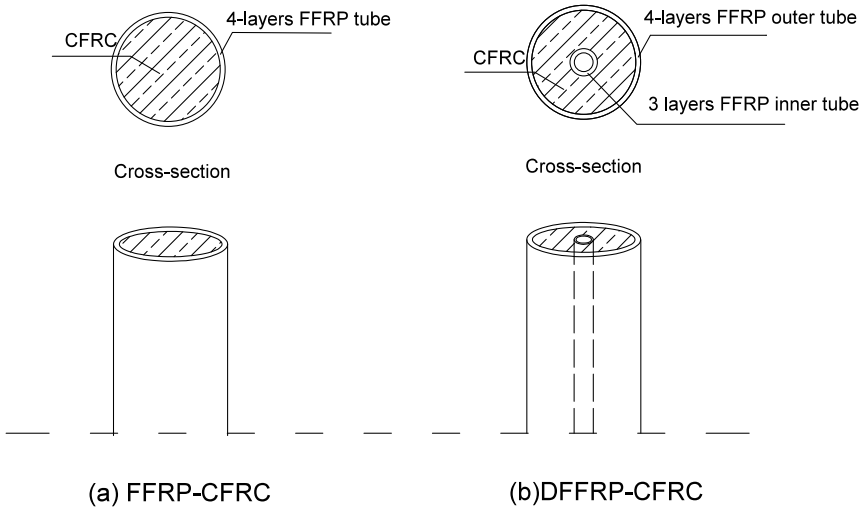

Figure 2 Two configurations: (a) FFRP-CFRC and (b) DFFRP-CFRC composites

METHODOLOGY

Test specimens

Six specimens were subjected to snap back, harmonic and earthquake loads. Half of them are FFRP-CFRC columns, and others are DFFRP-CFRC columns. All specimens and their dimensions are listed in Table 1. The diameter of the inner FFRP tube of DFFRP-CFRC is 25 mm.
The flax fibre reinforced polymer tubes of all specimens were fabricated using the hand lay-up process by wrapping around a PVC mould with an outer diameter of 100 mm and 1200 mm of length. For the outer FFRP tube, 4 layers of flax fabrics were considered. The inner FFRP tube considered 3 layers of flax fabric. The epoxy used the SP High Modulus Ampreg 22 resin with mix ration 100:26. All FFRP tubes completed at the Centre of Advanced Composites Materials at the University of Auckland. Each specimen has a length of 1000 mm and a concrete core of 100 mm diameter.

Table 1 All specimens tested under snap back, harmonic and earthquake loadings

Configuration	Thickness of outer FFRP tube (mm)	Thickness of inner FFRP tube (mm)
FFRP-CFRC	5.3	--
DFFRP-CFRC	5.3	3.05

For CFRC the mix ratio by weight is 1: 0.58: 3.72: 2.37 for cement: water: gravel: sand. The 50 mm length coconut fibres were added during the concrete mixing with a content of 1% of cement by mass. The designed compressive strength of the concrete is 25 MPa after 28 days of curing. In this paper only some of the responses to the earthquake loading is presented.

Instrumentation and test set-up

The test set-up for the snap back test, harmonic and earthquake load test is the same. The experimental model is considered as a single degree-of-freedom (SDOF) system. For each test, a composite column was fixed on the 10 kN shake table by a steel foundation (Figure 3). The support clamped the column to the shake table (Figure 4). The steel foundation was designed with a height of 15 mm, and each piece of steel foundation has a length of 380 mm and a width of 15 mm.

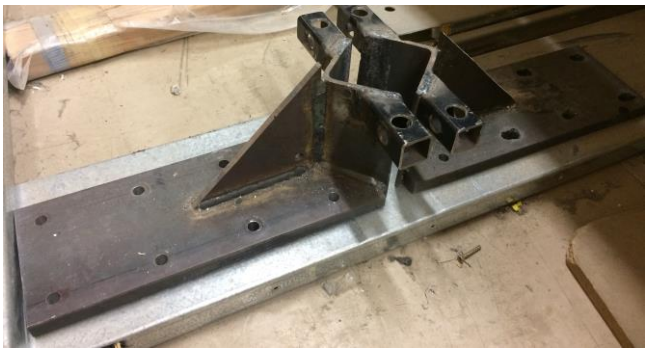

Figure 3 Steel supports

Figure 5 shows the sketch of the test set-up. On the top of the column, a wooden box was placed and fixed by two-piece of wooden clamp. This wooden box was filled with lead bricks to simulate the uniformly distributed mass. The added mass for each column is different, because a fundamental frequency for each column around 3 Hz was targeted. Since the stiffness and damping of each column are slightly different, an efficient way is to adjust the mass to achieve the targeted fundamental frequency. Four accelerometers were mounted at four different locations to record the corresponding accelerations. Two laser transducers were placed at top of the SDOF structure and on the shake table to measure the displacements (see Figure 5). Security framework was installed surround the shake table.

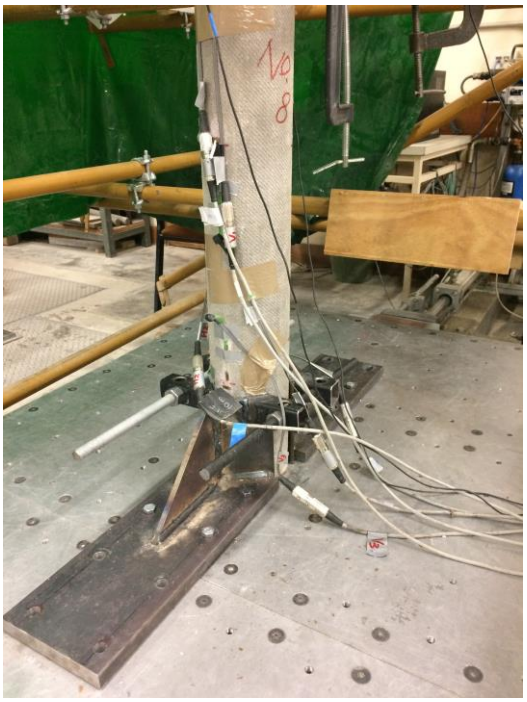

Figure 4 A composite column fixed to shake table with steel supports

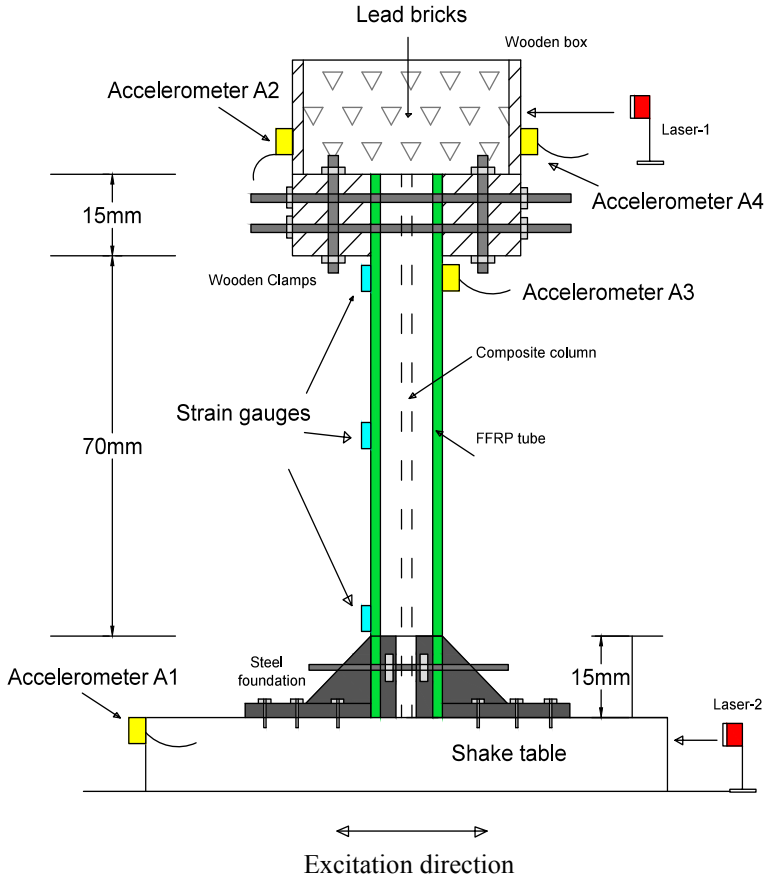

Figure 5 Sketch of test set-up of SDOF model

Ground excitation

To assess the seismic performance of a simple bridge pier made of FFRP tube confined CFRC core laboratory studies are conducted. For simplicity the bridge deck is simulated as a single degree-of-freedom (SDOF). The top mass is selected so that the fundamental frequency has a value of about 3 Hz. The actual frequency was 2.93 Hz. To achieve a fixed base boundary condition the base of the pier is held by two steel angles as shown in Figure 3. The free pier height is 70 cm (Figure 5). Figure 6 shows one of the ground displacement time histories simulated based on Japanese design spectrum for a hard soil condition (JSCE, 2000, Chouw and Hao, 2005). The peak ground displacement (PGD) of the ground motion (GM) is 30.82 cm.

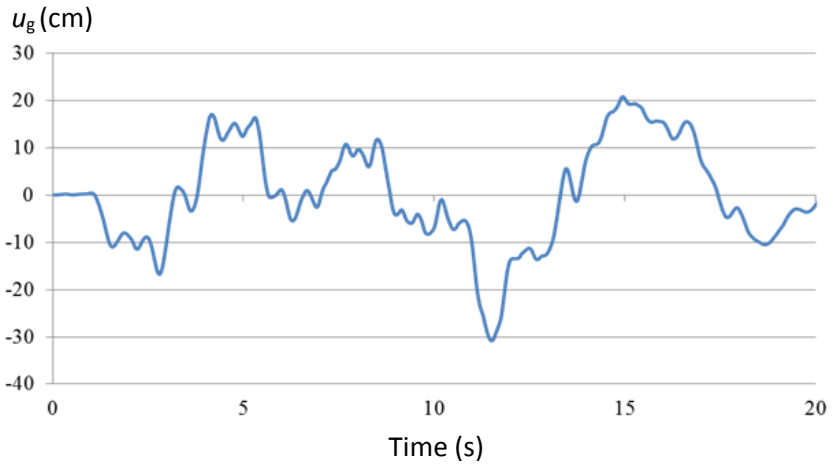

Figure 6 Ground excitation

Figure 7 displays the response spectrum of the corresponding ground acceleration and the target spectrum (bold dashed line). A response spectrum displays the maximum dynamic response of a number of SDOF structures due to the same ground excitation as a function of structural frequency and a particular damping ratio. The response spectrum of ground accelerations is often used, because it reveals directly the maximum acceleration a structure will experience during an earthquake and the maximum acceleration activated in a structure is proportional to the force that the structure has to withstand. Because the ground motions are simulated based on the same target spectrum, they have very similar frequency content. Although the time histories of the ground displacement look different, their frequency content matches well with that of the target spectrum.

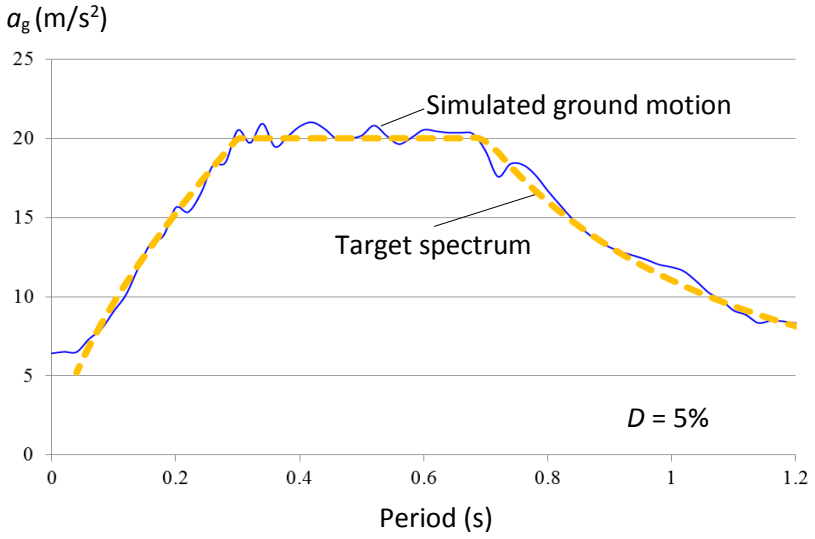

Figure 7 Response spectrum of ground motion

In order to reveal as much information as possible, the initial experiment was performed with a very small PGD of 20 mm, i.e. only 6.5% of the original ground motion excitation. The subsequent experiments were performed with a gradually increasing PGD of 55 mm, 70 mm, 80 mm and 90 mm.

RESULTS AND DISCUSSION

Figure 8 shows a comparison between the displacements at the top of the same FFRP-CFRC bridge pier due to the same ground motion with an assumption of undamaged (linear behaviour) and damaged bridge pier. The linear response is obtained from the experiment with a small PGD of 55 mm, while the nonlinear response is achieved with PGD of 90 mm. As anticipated the stronger the loading magnitude the larger the response amplitudes. In order to compare the two results, the linear response is multiplied by a factor of 1.6364. The response of the stiffer linear system can be clearly seen in a shorter period (solid line) in comparison with the nonlinear response (dashed line), e.g. in the time instants of around 9 s and 14 s.

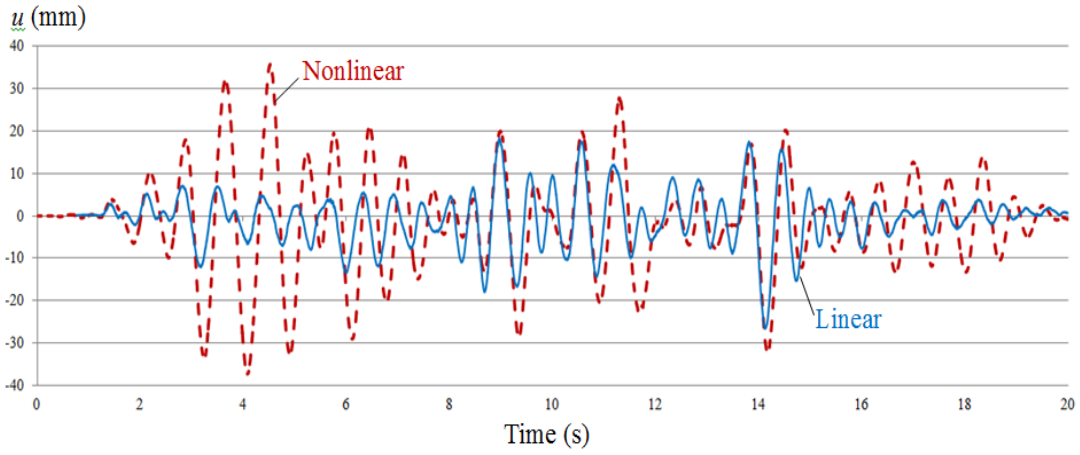

Figure 8 Influence of material nonlinearity on the response of the FFRP-CFRC composite structure due to GM with PGD 55mm and 90 mm

Figure 9 shows the influence of double FFRP tubes on the linear top displacement of the bridge pier. The ground motion PGD considered is 20 mm. The maximum response of the bridge pier with single and double FFRP tubes is -3.55 mm and 3.54 mm, respectively. Despite less CFRC materials are used in the case of double FFRP tube pier, the maximum displacements of both FFRP-CFRC and DFFRP-CFRC piers are as good as the same. These results show that double tube confinement has the potential to improve the seismic resistance of the structure. Despite less materials are used, almost the same seismic performance can be achieved. It is well known that less material means less inertia forces will be activated in the structures for the same loading.

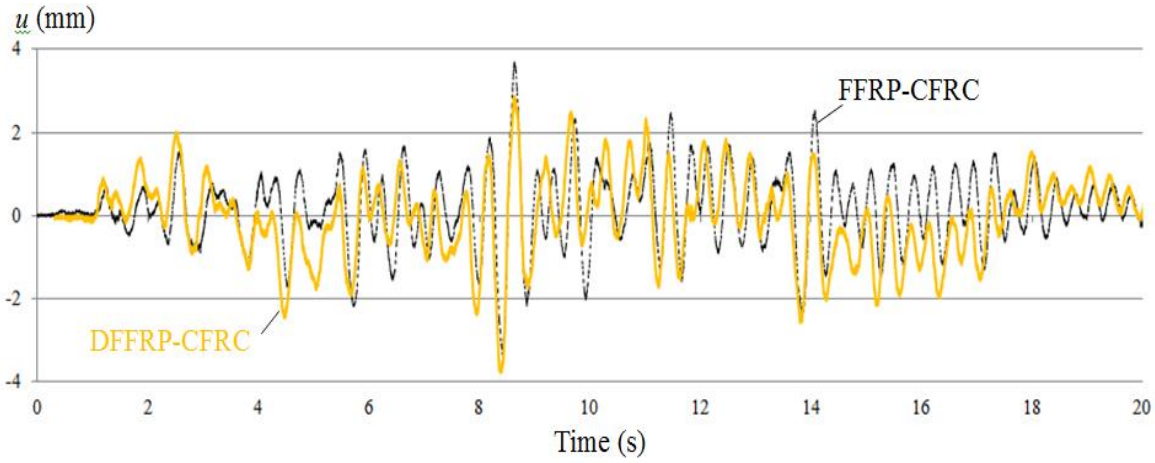

Figure 9 Influence of double tube confinement on the linear response of the structure due to GM with PGD of 20 mm

Figure 10 shows the effect of double FFRP tube confinement on the response of the structure due to a larger magnitude earthquake. The considered ground motion has a PGD of 80 mm. While a single FFRP tube confinement CFRC core composite bridge pier will already suffer damage, a double FFRP tube confinement manages to keep the bridge pier elastic. The solid and dashed-dotted lines are the horizontal displacement at the

top of the bridge pier with a single and double tube confinement, respectively. Despite remaining in elastic range the less material used in double FFRP tube confinement leads to a slightly larger maximum displacement in comparison with that of single FFRP tube confinement case.

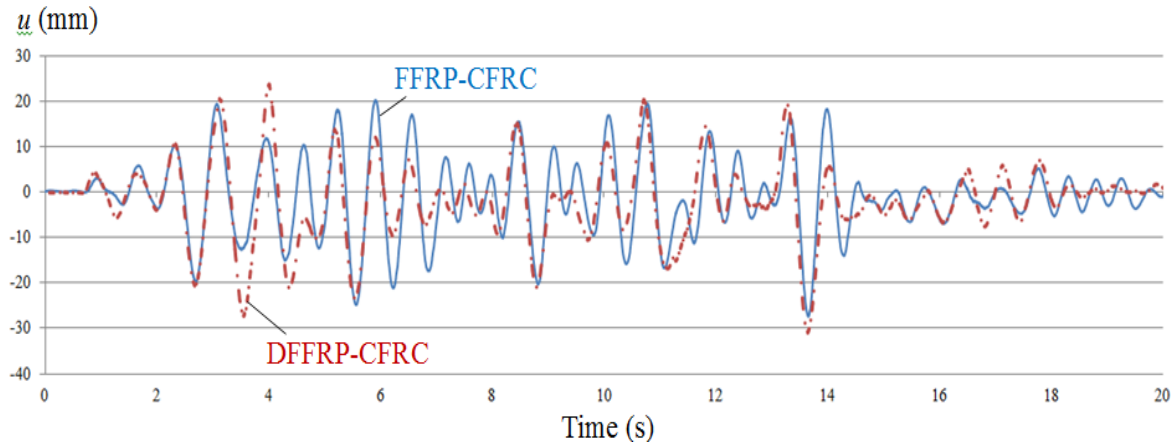

Figure 10 Influence of double tube confinement on the structural response due to GM with PGD of 80 mm

CONCLUSIONS

The seismic response of a flax fibre reinforced polymer and coconut fibre reinforced concrete composite bridge pier is investigated. The loading considered is the ground motions simulated based on Japanese design spectrum for a hard soil condition. The earthquake loading is simulated by a shake table.

The results show that

1. An assumption of linear elastic idealization of the system is not applicable for the complex FFRP-CFRC composite structures. For FFRP-CFRC composite structures a linear extrapolation of results obtained from low excitation cannot be used to obtain the response to a large magnitude excitation.
2. The usage of a double tube confinement can have a significant advantage, since less mass is considered. Despite less material is used in a linear excitation range double tube FFRP confinement can achieve similar seismic performance as single tube FFRP confined CFRC composite structure.

Blast/Impact Loading and Progressive Collapse

APPLICATION OF THE WORK-ENERGY PRINCIPLE TO ASSESS THE RISE-TIME EFFECT ON THE DYNAMIC RESPONSE AMPLIFICATION UNDER COLUMN LOSS

Meng-Hao Tsai [1,*]
[1] National Pingtung University of Science and Technology,
Department of Civil Engineering,
No.1 Hseuh-Fu Rd., Pingtung County, Taiwan.*Email:mhtsai@mail.npust.edu.tw

ABSTRACT

Progressive collapse analysis of building structures is usually performed under sudden column loss conditions. This means that the bearing capacity of the targeted column disappeared instantaneously. Hence, a time length less than one tenth of the natural period in the gravitational direction of the damaged structure has been recommended for disabling the targeted column in the numerical analysis. The time length required for disabling the postulated column in dynamic progressive analysis is defined as the rise time. Most seismically designed structural members may have a minimum ductility capacity as regulated in design codes. When the column is subjected to a devastating abnormal loading, it may gradually lose its load-carrying ability with increased deflection. Thus, the column strength is completely lost within a finite rise time. In other words, the dynamic loading for progressive collapse analysis of the remaining structure is increased gradually rather than instantaneously. This study intends to apply the work-energy principle to investigating the rime-time effect on the dynamic response amplification under column loss. A single-degree-of-freedom (SDOF) model is used to derive the analytical formulation with consideration of the rise-time effect. It is constructed with an assumption that the maximum imposed loading can be attained before yielding. Analytical procedures for calculate the force- and displacement-based dynamic increase factors (DIFs) are proposed. Nonlinear time-history analyses are then carried out to evaluate the accuracy of the proposed approach. The analysis results indicate that the dynamic amplification will decrease with increased finite rise time. The rise-time effect decreases with increased plastic demand. For practical application, the rise-time effect may be reasonably neglected as the ductility demand is larger than 5.0 and the normalized loading is larger than 1.5 for the force- and displacement-based DIFs, respectively. Its influence on the column-loss response may vary with the ratio of the rise-time length to the natural period and the extent of plastic deformation.

INTRODUCTION

Progressive collapse vulnerability of building structures has become an active research topic since the 9/11 terrorist attack on the World Trade Center in 2001. In fact, the earliest study regarding the progressive collapse of buildings may be traced back to the partial collapse of Ronant Point Apartment Building in England, 1968. The incident highlighted the importance of structural integrity and robustness against local structural failure. As revealed from several structural design codes, special attention has been paid to the structural integrity (Mohamed 2006). Also, different measures for reducing the risk and hazard of progressive collapse were investigated. In general, provision of tie force, alternative load path, integrity, and specific local load resistance has been recommended as feasible measures for reducing the vulnerability of building structures to progressive collapse (Abruzzo *et al*. 2006; Ellingwood 2006; Nair 2006). Since the cause, reoccurrence, and intensity of abnormal loadings for triggering the progressive collapse are difficult to predict precisely, provision of threat-independent alternative paths for loading transfer is regarded as an acceptable and popular solution among those proposed measures. Alternative load paths of a damaged building structure may be verified by assessing its load transfer ability under stipulated column loss scenarios. Practical progressive collapse analysis procedures have been recommended by the US General Service Administration (GSA 2013) and Department of Defense (DoD 2009). Two different load magnification factors, namely the load increase factor (LIF) and dynamic increase factor (DIF), are used to consider the dynamic effect in the linear static (LS) and nonlinear static (NS) analysis procedures, respectively. Empirical formulae obtained from nonlinear dynamic (ND) analyses of various frame models subjected to column loss are used to predict the LIFs and DIFs in the guidelines (DoD 2009).

Usually, progressive collapse analysis of building structures is performed under sudden column loss conditions. This means that the bearing capacity of the targeted column is lost instantaneously. Hence, a time length less than one tenth of the natural period in the gravitational direction of the damaged structure is suggested for disabling the targeted column in the numerical analysis. Complying with the postulation of sudden column loss, the principle of equal work and energy has been used to estimate the collapse resistance of the damaged building frames (Tsai and Lin 2008). The energy-based concept was also used to develop analytical expressions for the DIFs (Tsai 2010) and a performance-based retrofit design approach for regular building frames (Tsai 2012). Also, Menchel *et al*. (2011) proposed a methodology to identify the static pushover procedure for sudden column removal by using a similar energy criterion. Fang *et al*. (2013) used the energy-based concept to evaluate the robustness of steel-composite car parks under vehicle fire. Most of these studies were carried out on the basis of sudden column loss condition.

The time length required for disabling the postulated column in dynamic progressive analysis is defined as the rise time. For seismically designed buildings, most structural members may have a minimum ductility capacity as regulated in design codes. When the building column is subjected to a devastating abnormal loading, it may lose its load-carrying ability under gradually increased deflection. That is the column strength is completely lost with a finite rise time. In other words, the external loading for progressive collapse analysis is imposed gradually, instead of instantaneously. Some studies have been carried out to investigate the rise-time effect on the structure response under column loss. Liu *et al*. (2005) indicated that the time length for completely removing the column could affect the structural response and the rate of removal would be insignificant in the final results as the rise time was less than 10 ms. Gudmundsson and Izzuddin (2010) investigated whether the assumption of sudden column loss is realistic and whether the scenarios can reflect an actual extreme event. They concluded that the sudden column loss is a useful design scenario for assessing structural robustness and may result in an upper bound of the deformation under blast events. Rahai *et al*. (2013) compared the instantaneous and gradual column-removal responses of an RC structure and revealed that the former induced higher stress and deformation demand on the structure. So far, most studies regarding the rise-time effect were mainly carried out with dynamic time-history analyses. This study intends to apply the energy-based method to investigation of the rime-time effect on building response under column loss. At first, how the rise time can influence the dynamic column-loss response is described. Analytical formulation with consideration of the rise-time effect is derived for the pseudo-static response of an elasto-plastic single-degree-of-freedom (SDOF) model. Procedures for calculating the force-based and displacement-based DIFs of the SDOF model are proposed. Nonlinear time history analyses for the column-loss response of a SDOF and a clamped beam models are then carried out to verify the accuracy of the proposed procedures.

PROBLEM DESCRIPTION

As recommended in the GSA and DoD guidelines, the alternate load-path analyses are proceeded with a presumed sudden column loss condition, which may be regarded as completely brittle failure induced by a localized extreme loading. However, if the column is designed with excellent ductility, it may lose its bearing capacity in a finite length of time. In other word, the column can lose its stiffness and strength gradually instead of suddenly. Two mathematical expressions may be considered to describe this kind of dynamic column loss scenarios. The first one assumes it as an intact structure subjected to an existing constant gravitational loading and the stiffness of the presumed column deteriorates gradually. The equation of motion is expressed as

$$\frac{P_u}{g}\ddot{u}+[k+k_0(1-(t/t_r)^n)]u=P_u \tag{1}$$

where P_u is the sustained axial load of the column and u is the deflection at the joint of the two-span beams bridging over the failed column. k_0 and k respectively designate the stiffness of the column and the adjacent remaining members. t_r is the rise time for the completely column failure and n is a positive exponent describing the deteriorating rate of the column stiffness. Alternatively, when the stiffness and strength of the damaged column deteriorates in the failure process, it means that the originally sustained loading of the column is gradually imposed to the column-removed frame. Hence, in this regard, the equation of motion may be written as

$$\frac{P_u}{g}\ddot{u}+ku=P_u\left(\frac{t}{t_r}\right)^n \tag{2}$$

In the formulations of Eq.1 and Eq.2, it is assumed that either the stiffness deterioration or the loading growth is varied exponentially. Also, in the equations, the imposed loading will contribute to the vibration period of the damaged structure in the gravitational direction. Since Eq.2 is simpler to solve for analytical expressions than Eq.1, it is thus used as the first step to investigate the effect of rise time on the dynamic amplification of column

loss scenarios in this study. Although the loading growth is expressed in an exponential form, a linearly increased loading, namely n= 1.0, is adopted to further simplify the analytical investigation.

ANALYTICAL DERIVATION

From the aspect of work and energy, regardless of the loading rate, the strain energy of a structural frame may be described by a general elastic-plastic load-deflection model, as shown by the bilinear curve OCD in Figure 1. However, the work done by an instantaneously imposed loading will be different from that by a gradually increased loading. This is because that the former can be regarded as the product of the loading magnitude and the deflection, while the latter may present nonlinear load-deflection relation as shown by the curve OBE in Figure 1. For a single degree-of-freedom (SDOF) system subjected to a constant loading with linear growth rate, the equation of motion during the loading growth phase may be expressed as

$$\frac{P_u}{g}\ddot{u} + ku = P_u \frac{t}{t_r} \qquad t \le t_r \tag{3}$$

In this phase, the steady-state displacement time history can be obtained as

$$u(t) = \frac{P_u}{k}\left(\frac{t}{t_r} - \frac{\sin \omega_n t}{\omega_n t_r}\right) \quad t \le t_r \tag{4}$$

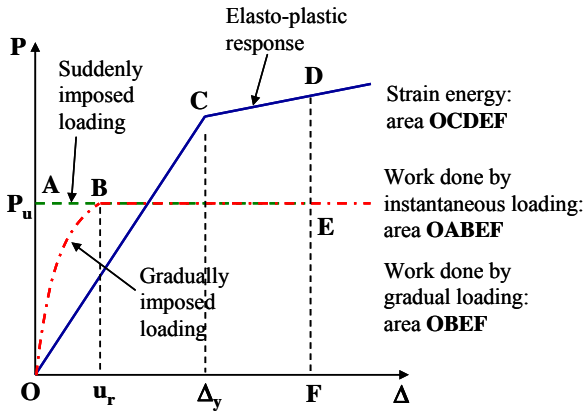

Figure 1 A schematic of the load-deflection curves for strain energy and external work

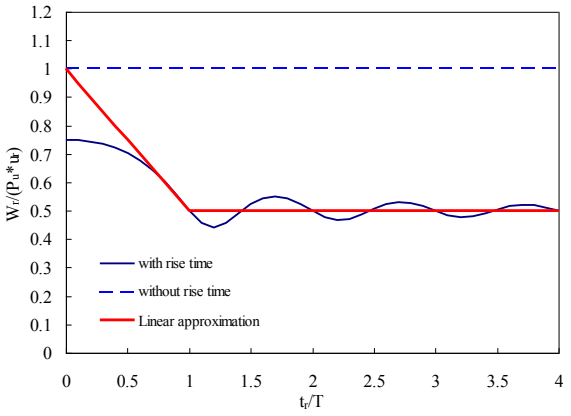

Figure 2 Variation of the normalized external work in the loading phase

If the column-removed frame is not loaded into the inelastic range during the loading phase, which actually holds under most conditions, Eq.4 could be used to estimate the corresponding external work. The work done by the loading is calculated as

$$W(t) = \int P_u \frac{t}{t_r} du \,, \tag{5}$$

which leads to

$$W(t) = \frac{P_u^2}{k}\left(\frac{t^2}{2t_r^2} - \frac{t \sin \omega_n t}{\omega_n t_r^2} - \frac{\cos \omega_n t - 1}{\omega_n^2 t_r^2}\right) \text{ for } t \le t_r \,. \tag{6}$$

The above result can be used to estimate the work done at $t = t_r$. Let u_r represent the displacement at $t = t_r$. A numerical investigation on the relationship of $W(t_r)/(P_u u_r)$ and t_r/T is shown in Figure 2. It is seen that when $t_r/T > 1$, $W(t_r)/(P_u u_r)$ is neutralized about 0.5 with very small oscillation. Also, since a step function is used to describe the imposed loading for sudden column loss, the value of $W(t_r)/(P_u u_r)$ will be 1.0 if $t_r/T = 0$. Therefore, as shown in the figure, a piece-wise linear approximation for the work done at $t = t_r$ is made and expressed as

$$W(t_r) = \beta P_u u_r \tag{7}$$

where

$$\beta = 0.5 \text{ for } t_r/T > 1 \tag{8a}$$

and

$$\beta = 1 - 0.5 t_r/T \text{ for } 0 < t_r/T \le 1 \,. \tag{8b}$$

Moreover, according to the loading growth definition, the applied loading reaches the maximum magnitude P_u as the displacement is larger than u_r. Hence, the total external work may be expressed as

$$W_U = P_u(\Delta_u - u_r) + \beta P_u u_r \tag{9}$$

where Δ_u is the maximum displacement. For an assumed elasto-plastic SDOF model with post-yield stiffness ratio α, as shown in Figure 1, the stored strain energy is written as

$$E_S = \frac{1}{2} P_y \Delta_y [\alpha(\mu - 1)^2 + 2\mu - 1] \tag{10}$$

where P_y and Δ_y are the yielding force and displacement of the SDOF model and μ is the ductility demand under the external loading P_u. From the equal-work-and-energy theorem, $W_u = E_S$ leads to

$$R = \frac{P_u}{P_y} = \frac{\alpha(\mu - 1)^2 + 2\mu - 1}{2[\mu - (1 - \beta)\mu_r]} \text{ for } \mu > 1.0, \tag{11}$$

where $\mu = \Delta_u / \Delta_y$ is the ductility demand and $\mu_r = u_r / \Delta_y$. Eq.11 is the normalized pseudo-static loading of the elasto-plastic SDOF with the rise-time effect. It may also be used to determine the ductility demand under dynamic column loss as

$$\mu = \frac{(R + \alpha - 1) + \sqrt{(R + \alpha - 1)^2 - \alpha[2R(1 - \beta)\mu_r + \alpha - 1]}}{\alpha} > 1.0 \tag{12}$$

Since elastic response is assumed for the loading phase in the analytical derivation, it implies that the value of u_r should be less than the yield displacement. That is $\mu_r \le 1.0$ in Eq.11 and Eq.12. The influence of this assumption will be assessed in the later numerical verification.

PROCEDURE FOR THE DYNAMIC INCREASE FACTORS

For regular building frames, the dynamic structural response under column loss is usually dominated by a single deformation mode. The relation between the sustained loading and the displacement of the column-removed joint can be captured by an equivalent SDOF model (Sasani and Sagiroglu 2008). Therefore, the analytical normalized pseudo-static loading and dynamic ductility derived in the previous section may be used to estimate the force-based and displacement-based DIFs with rise-time effect for progressive collapse analysis of building frames.

Force-based DIF

The forced-based DIF is determined based on a given ductility or displacement demand. With a given ductility demand and a finite rise time t_r, the following steps can be proceeded to find the DIF.

Step 1: Estimate the displacement at $t = t_r$ and calculate $\mu_r = u_r / \Delta_y$.

Step 2: If the ductility demand μ is not larger than 1.0, the required normalized static loading is determined as

$$R_S = k\mu\Delta_y / P_y = \mu. \tag{13}$$

Calculate the t_r / T ratio and the elastic dynamic amplification factor (Chopra 1995) will be used for the DIF as

$$DIF_P = 1 + \frac{|\sin(\pi t_r / T)|}{\pi t_r / T}. \tag{14}$$

Step 3: If μ >1.0, the required normalized static loading is determined as

$$R_S = 1 + \alpha(\mu - 1). \tag{15}$$

With the value of t_r / T, the value of β is obtained from Eq.8. Then, the normalized pseudo-static loading is determined from Eq.11.

Step 4: The forced-based DIF is calculated as R_S / R.

Displacement-based DIF

The displacement-based DIF on the other hand is determined based on a given external loading P_u. With the given loading and a finite rise time t_r, the following steps may be proceeded to find the DIF.

Step 1: Calculate $R = P_u / P_y$. If $R \le 0.5$, the structural response is elastic and the DIF will be the same as Eq.14.
Step 2: If $0.5 < R \le 1.0$, the structural response is elastic as the loading is statically applied and inelastic as the loading is dynamically applied. The static ductility demand is then written as

$$\mu_s = \frac{P_u / k}{\Delta_y} = R \tag{16}$$

and the dynamic ductility demand is obtained from Eq.12.
Step 3: If $R > 1.0$, the static ductility demand is obtained from

$$\mu_s = \frac{R-1}{\alpha} + 1 \tag{17}$$

and the dynamic ductility demand is obtained from Eq.12.
Step 4: The displacement-based DIF is then calculated as μ / μ_s.

NUMERICAL VERIFICATIONS

SDOF model

In this section, a SDOF model is constructed to verify the accuracy of the proposed analytical formulation. An elasto-plastic nonlinear spring with yield force P_y = 51.5 kN, yield deflection Δ_y = 0.7 cm, and a post-yield stiffness ratio α = 0.05 are assumed for the SDOF model. Thus, its elastic stiffness is equal to 73.57 kN/cm. The imposed loading magnitude is varied in terms of a multiplier of the yield force P_y. Nonlinear time-history analyses are carried out for the SDOF model subjected to the constant loading function with finite rise time. The loading magnitude is changed from 0.2 P_y to 3.0 P_y in the nonlinear time-history analyses. Since the imposed loading is considered as the vibration mass in the time-history analyses, the natural period of the model will increase with the loading magnitude. Three different rise time, namely t_r = 0.06, 0.10, and 0.15 sec, are considered in the analyses. The smallest rise time will result in all the values of t_r / T smaller than 1.0. However, some of the t_r / T ratios will be larger than 1.0 in the analyses with the other two larger rise time.

Figures 3a and 3b show the force- and displacement-based DIFs of the SDOF model, respectively. In the figures, the symbols represent the DIFs obtained from the nonlinear dynamic time-history analyses, while the curves represent those obtained from the proposed analytical procedures. Also, the analytical DIFs obtained without considering the rise-time effect (Tsai 2010) are included in the figures for comparison. In Figure 3a, it is observed that the force-based DIF decreases with increased t_r. This indicates that the applied loading may be overestimated in static progressive collapse analysis without considering the rise-time effect. Nevertheless, the difference induced by the rise-time effect reduces for larger ductility demands, which implies less influence on the plastic column-loss response. Also, the dynamic time-history analysis results match well with the predicted DIFs. Furthermore, in the UFC 4-023-03 progressive collapse analysis guidelines, it is recommended that the t_r / T should be less than 0.1 for sudden column loss scenarios. As shown in Figure 4a, the values of t_r / T in the numerical demonstration are larger than the threshold and the proposed approach may serve as a measure to account for the rise-time effect. In the analytical derivations, elastic behavior is assumed for the load-increasing phase. Figure 4b shows the variation of the ductility demands, μ_r, at the time instant $t = t_r$. It is seen that μ_r is less than 1.0 as t_r = 0.06 sec, while it may be larger than 1.0 as t_r = 0.10 or 0.15 sec. Nevertheless, the analytical approach still provides accurate prediction even when μ_r is larger than 1.0. This means that the assumption of $\mu_r \le 1.0$ is not critical to the prediction of DIFs.

On the other hand, the displacement-based DIFs with varied normalized loading P_u / P_y are shown in Figure 3b. Similar to the force-based DIFs, the displacement-based DIF decreases with increased t_r. Also, it is observed that the influence of rise time on the displacement-based DIFs can be neglected as P_u / P_y is larger than 1.5. This may be interpreted by the gradually decreased t_r / T with increased P_u / P_y, as shown in Figure 5a. Apparently, a larger imposed loading leads to an increased natural period T and thus reduces the rise-time effect. In addition, the predicted displacement-based DIFs agree well with the numerical analysis results even

though the assumption of elastic behavior in the load-increasing phase may be violated as P_u / P_y is larger than 1.0 for the cases of t_r = 0.10 and 0.15 sec, as shown in Figure 5b.

Clamped beam model

In the nonlinear dynamic analyses of the SDOF model, the originally supported loading of a failed column is completely applied to the model without load redistribution. In general, there are always adjacent structural members or boundaries to share the supported loading of the failed column in a real building frame. For one-

step closer to the real situation, the proposed analytical formulations are further applied to a clamped steel beam model. The steel beam has an ASTM W24x68 section made of A572 Grade 50 material. A combined mid-span and uniformly distributed loading, Q + qL, is imposed on the clamped beam, as shown in Figure 6a. The mid-span concentrated loading, Q, is equal to half the distributed loading, qL. Yield reaction P_y for a three-hinge mechanism is equal to 1440 kN at an equivalent yield displacement of 1.80 cm. Lumped flexural hinges are assigned at the mid-span and beam ends. An elasto-plastic nonlinear model with a post-yield stiffness ratio of 0.05 is assumed for the hinge properties. Dynamic time-history analyses are conducted by applying an equal-and-opposite mid-span loading to counteract the original supporting load Q+qL/2. The counteractive loading is linearly increased within the rise time t_r, as shown in Figure 6b. Three different finite rise time and some selected normalized imposed loadings are considered for the time-history analyses.

The numerical and predicted DIFs are compared in Figures 7a and 7b. It is seen that the proposed approach may give satisfactory predictions in both the force- and displacement-based DIFs. The rise-time effect on the clamped beam appears similar to that on the SDOF models. Insignificant effects on the force- and displacement-based DIFs are observed as the ductility is larger than 5.0 and the normalized loading is larger than 1.5, respectively. It is reminded that a larger imposed loading is concurrent with an increased ductility demand and structural period under column loss. With a larger ductility or loading demand, the t_r/T ratio decreases and then leads to smaller rise-time effect on the significantly plastic response. However, the analytical formulation is derived from a SDOF model subjected to direct loading, which is different from the partial loading release condition of the clamped beam model (Tsai 2012). Hence, the accuracy is not as good as the SDOF case. Moderately increased error can be observed for the displacement-based DIF at the vicinity of P_u/P_y=1.0 as t_r = 0.3 sec. In general, the analytical approach leads to slightly larger DIFs than the numerical analysis. In addition, Figures 8a and 8b show the variation of t_r/T with the ductility demand and normalized loading, respectively. Most of the t_r/T ratios are larger than 1.0 for the case with t_r = 0.3 sec. It is seen that as t_r/T is close to or larger 1.0, the DIF becomes close to or only slightly larger than 1.0, as observed in Figure 7a and for P_u/P_y <1.0 in Figure 7b. This factor results in similar elastic dynamic amplifications for the cases with t_r = 0.15 and 0.30 sec. Therefore, as t_r/T being larger than one, the dynamic effect reduces and column loss response becomes dominated by quasi-static behavior. The elastic-to-moderately plastic dynamic response will decrease and the DIF will converge asymptotically toward 1.0.

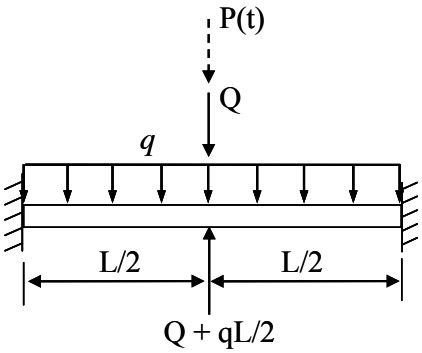

Figure 6a The clamped beam model

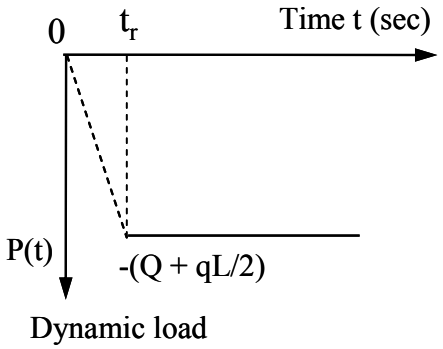

Figure 6b The loading time history

Practical consideration

As revealed in the current design guidelines issued by the GSA (2013) and DoD (2009), a force-based DIF is used to amplify the imposed loading combination in the nonlinear static progressive collapse analysis. The deformation demands under the amplified loadings are then compared with the deformation capacities of members. According to the GSA and DoD guidelines, the ratio of allowable plastic rotation to yield rotation may be used as the ductility demand, μ, in the analytical formulation. The smallest ductility demand for any primary element, component, or connection of the members in the tributary area of the failed column is chosen for determining the DIF of the entire building frame. From the previous numerical investigations, the rise-time effect may be neglected as the ductility demand is larger than five for the forced-based DIF. Regarding the length of the rise time, it is related to the external loading duration, allowable plastic rotation, and dimensions of the failed column, which is not included herein.

CONCLUSIONS

This study aimed at clarifying the rise-time effect on the dynamic amplifications of building structures under column loss. The work-energy principle, which had been successfully used in evaluating the progressive collapse resistance of building structures, was applied to the analytical formulation of the pseudo-static response with the rise-time effect. An assumption of elastic loading phase was made in the derivation. Analytical procedures were proposed to determine the force- and displacement-based dynamic increase factors (DIFs) with the rise-time effect. Numerical time-history analyses of a SDOF and a clamped beam model verified that the proposed analytical procedures could appropriately consider the rise-time effect and accurately predict the dynamic amplifications in both the displacement and force responses. The assumption was shown to have insignificant influence on the accuracy. Analysis results indicated that both the force- and displacement-based DIFs decreased with increased rise time. Also, the dynamic structural response under column loss decreased with consideration of the rise-time effect. Nevertheless, its influence was reduced as significant plastic response occurred. For practical application, the rise-time effect may be reasonably neglected as the ductility demand is larger than 5.0 and the normalized loading is larger than 1.5 for the force- and displacement-based DIFs, respectively. Hence, as significant plastic response is allowed, the rise-time effect can be neglected in the progressive collapse design and analysis. If moderate plastic response is the performance target, the rise-time effect can be considered to avoid overestimation as the ratio of t_r/T is larger than 0.3. As for elastic response, it is suggested to consider the rise-time effect as t_r/T >0.1, which is the upper bound for numerical simulation of sudden column-loss scenarios in the GSA and DoD guidelines.

ABSTRACT

Progressive collapse of structures caused by extreme or accidental loads may lead to significant loss of life and property. Considerable research efforts have been made to date to mitigate the probability of progressive collapse and its consequences. This study summarises the fundamentals of progressive collapse in relation to the existing theoretical concepts and understanding. Specifically the existing theories pertinent to progressive collapse of building structures, in particular reinforced concrete (RC) flat plates, are examined from the following four key aspects: (1) definition of progressive collapse from deformation and/or strength perspectives with respect to the failure criteria of structural members and the entire structural system; (2) failure mechanisms of load-bearing systems undergoing progressive collapse with respect to the structural ultimate capacity, which has not been considered in the design process; (3) research methodologies for investigating collapse mechanisms, with emphases on experimental and numerical approaches; and (4) collapse-resistant design principles as covered in several international design standards in which a number of robustness requirements have been recognised. Based on the schematic review of the current trends and developments, gaps and limitations in progressive collapse research are identified and a new research direction is established to advance the progressive collapse study of RC flat plate structures.

KEYWORDS

Progressive collapse, flat plate structures, collapse mechanism, collapse-resistant design and evaluation.

INTRODUCTION

Progressive collapse is initiated as a consequence of local damage resulting in a chain effect throughout the structure and its elements, thereby leading to a disproportionately large extent of failure (Ellingwood 2006; Keyvani *et al*. 2014). The failure growth is due to the stable load transfer paths being disturbed within the structure. The study on the progressive collapse resistance was initiated due to the gas explosion of Ronan Point Tower in 1968. Further justification and development of the principles was promoted by the truck bombing attack of Alfred P. Murrah Federal Building in 1995 and the 9/11 tragedy of the World Trade Center in 2001. For flat plate systems in particular, the Sampoogn Department Store collapse in 1995 (Figure 1a) claimed the life of more than 500 people with 937 injures. The Pipers Row car park collapse in 1997 (Figure 1b), although with no casualties, still caused considerable economic loss and social concerns. These two collapse cases highlighted the significance of understanding the triggering punching shear failure of RC flat plate structures as well as the resulting load transfer patterns when a progressive collapse occurs (Park 2012; Wood 2003).

(a) Sampoong Department Store collapse (Park 2012)

(b) Pipers Row car park collapse (Wood 2003)

Figure 1 RC flat plate structures collapses

To date a significant achievement relevant to progressive collapse studies has been made. Accordingly, several countries including the USA, UK, and China, have compiled the required standards and guidelines attempting to mitigate the progressive collapses in their building designs. However, the majority of the existing knowledge is pertinent to frame structures whilst the understanding of progressive collapse in RC flat plate structures is limited. Given that RC flat plates are a popular construction type in Australia and worldwide, extra efforts towards progressive collapse research on such systems are timely required.

Four key aspects associated with the progressive collapse research can be identified: (1) failure criteria of progressive collapse, (2) failure mechanisms of load-bearing systems undergoing progressive collapse, (3) methodologies for investigating collapse problems, and (4) collapse-resistant design principles. This study aims to investigate these key aspects with an emphasis on RC flat plate structures. Through a schematic review of the current trends and developments, latest achievements in the progressive collapse research field are presented. Additionally, gaps and limitations are identified and a new research direction is established for advanced progressive collapse study of RC flat plates.

FAILURE CRITERIA DEFINING PROGRESSIVE COLLAPSE

The failure criteria considered in structural analysis are typically investigated from three levels: material, elemental, and structural. In particular, the progressive collapse analysis mostly focuses on the elemental and structural levels. This is principally due to the element-based damage propagation and ultimately the global structural failure due to the loss of vertical load-bearing element(s) at the local regions.

To assess whether an element fails or otherwise, appropriate collapse-related failure criteria must be established, i.e. elemental failure criteria. Based on their failure types, the elements can be categorised as deformation controlled or strength controlled. For deformation controlled element types, a certain number of elements which exhibit ductile properties, e.g. forming a plastic hinge after yielding, are still capable of bearing loads and accommodating deformation. Under this situation, the elemental deformation criterion should be applied. For strength controlled element types, on the other hand, when the elements exhibit brittle behaviour by losing load-bearing capacity rapidly after yielding, the elemental strength criterion should be applied. Given that the residual strength of elements exists in most element failure cases, it would be more appropriate to employ the deformation criterion. Nevertheless, the new ASCE 41 (2013) distinguishes the forces (e.g. axial load, shear, and moment) acting on the elements as deformation controlled or force controlled actions. This requires that the elemental deformation and strength must be assessed individually under each action.

Elemental Deformation Criterion

The elemental deformation criterion refers to the failure of elements if their deformations (displacements and rotations) exceed the corresponding allowable limits. An application of the deformation criterion is given in the General Services Administration (GSA) (2003) standard where ductility ratios and plastic hinge angles are used as performance indicators in the nonlinear analysis. The ductility ratios refer to as the ratios of the maximum deflections to the corresponding yield deflections at strategic points. While the plastic hinge angles refer to as the ratios of the maximum deflections to the corresponding span lengths. In order to align with the specifications in ASCE 41 (2013) and DoD (The Department of Defense) (2013), the new GSA (2013) standard adopts the same analysis procedures using the plastic rotation (hinge) angles as the acceptance criteria with minor modification in the nonlinear analysis. For RC structures, plastic hinges in general can be efficiently formed at element interconnections.

Elemental Strength Criterion

The elemental strength criterion denotes that the elements have failed if their maximum internal forces exceed the corresponding allowable limits. The GSA standard (2003) applies the strength criterion in the form of the Demand-Capacity Ratios (*DCR*) method for linear analysis. The *DCR* can be calculated using Eq. 1.

$$DCR = \frac{Q_{UD}}{Q_{CE}} \tag{1}$$

where, Q_{UD} is the acting force (demand) determined in component or connection/joint (moment, axial force, shear, and possible combined forces), Q_{CE} is the expected ultimate, un-factored capacity of the component or connection/joint (moment, axial force, shear, and possible combined forces).

In the latest version of DoD and GSA guidelines against progressive collapse, the *DCR* is considered as a prerequisite for employing linear analysis of buildings with irregularity features (DoD 2013; GSA 2013). Alternatively, simplified force controlled criteria for both linear and nonlinear analysis procedures are recommended as shown in Eq. 2, following the load and resistance factor design principles.

$$\phi Q_{CL} \geq Q_{UF} \tag{2}$$

where, Q_{UF} is the force-controlled action, Q_{CL} is the lower-bound strength of an element, and ϕ is the strength reduction factor.

Elemental Failure Criteria Used in Numerical Analyses

Lu *et al*. (2011) proposed a set of elemental failure criteria that can be used in numerical analyses of RC building structures, which is also applicable to flat plates. In the analyses, fibre beam and multi-layer shell elements were often used. The elemental failure criteria were introduced based on the predefined material failure criteria:

(1) For column or shear wall elements, the tension reinforcement is considered to have failed when the ultimate tensile strain of steel is reached. The compression reinforcement is considered to have failed when its compressive strain exceeds the maximum attainable strain in compression (concrete crushing). Consequently, if all of the reinforcement fibre or layer elements fail, then the column or shear wall is considered to have failed.

(2) Beam or slab elements are considered to be in compressive state at the small deformation stage and in tensile state at the large deformation stage. In addition to the tension reinforcement, the compression reinforcement is also able to provide tensile load-bearing capacity at the large deformation stage. Therefore, only if all of the reinforcement fibres or layers fail in tension, can the beam or slab elements be considered failed.

Structural Failure Criteria

The structural failure criteria determine if the progressive collapse is likely to occur from a structural level point of view. Mitchell and Cook (1984) utilised 0.15 times of the shorter span in slab structures as the allowable mid-span deflection, i.e. the threshold for progressive collapse. The DoD (2005) indicates that after the loss (removal) of elements due to the initial local damage, the extent of subsequent damage propagation can be used as an indicator to assess the severity of structural collapse. The DoD also stipulates that subsequent to the removal of an exterior column, the failure region of its upper structure shall not exceed the lesser value of 15% of the total floor area or 70m^2. When an interior column is removed, the failure region of its upper structure shall not exceed the lesser value of 30% of the total floor area or 140m^2. However, in the later version published in 2013, the DoD no longer requires the failure assessment at the structural level. Instead, the damage propagation limits are restricted to the following: the plastic deformation of the remaining structure shall not exceed the elemental failure criteria as aforementioned.

FAILURE MECHANISMS PERTINENT TO RC FLAT PLATES

An RC flat plate structure is a typical load-bearing system with compromised structural continuity and ductility (Ellingwood 2006). It is inherently more vulnerable to progressive collapse when compared with other ductile structural systems, such as moment resisting frame structures (Ellingwood 2006; Hawkins and Mitchell 1979; Qian and Li 2013a). This is largely because the system has no beams to facilitate redistribution of loads if local damage occurs.

Failure of an RC flat plate can generally be attributed to flexural or shear. Flexural failure arises in the spans of slab where significant deflection and cracking of concrete occurs. Moreover, this type of failure only occurs when the flexural reinforcement in the mid-span is inadequate and the shear reinforcement at the restrained ends of the slab is relatively heavily arranged. Shear failure, conversely, is distinguished by two possible modes: (1) a wide beam-shear failure or (2) a punching shear failure (Hawkins and Mitchell 1979). The wide beam-shear failure mostly occurs in corner column areas with the slab exhibiting flexural failure characteristics and a diagonal crack line cutting through the slab corner. Preventing this type of failure is commonly achieved through increased slab depth while decreasing the slab width to depth ratio within allowable ranges. Majority of current design standards deliver a conservative design of slab-column connections so that beam-shear failures can be prevented. It is an area where future research can be conducted to facilitate the design to be more cost effective. The punching shear failure, being the most critical type of shear failure, is discussed below.

Punching Shear Failure in RC Flat Plates

Hawkins and Mitchell (1979) and Keyvani *et al*. (2014) suggested that the area most likely to trigger progressive collapse of a flat plate structure is the interior slab-column joint, primarily due to punching shear failure. If such a failure brings the inability of the interior column to bear load (i.e., column loss), the gravity loading previously taken by this column will be redistributed. Such will cause load concentrations as well as large deformations at the region of the slab-column joint. Extra bending moment and shear are also generated in this region. Moreover, the adjoining slab will experience a torsional action. Combination of these induced forces results in severe stress concentration at the slab-column joint region, likely leading to a punching shear failure (Liu *et al*. 2015).

The punching shear failure begins when flexural cracks appear around the columns. These cracks propagate in an inclined direction to form a critical shear surface. Aggregate interlocking and dowel action work together to transfer shear before the critical shear surface is allowed to go through the entire slab thickness (Keyvani *et al*. 2014), upon which, a punching shear cone forms above the column. Meanwhile, the strength of concrete is reduced and the load is gradually transferred to the continuous reinforcement. Subsequently, the punching shear failure propagates from the current joint to the other regions of the structure (mainly the slab), due to moments not being able to be effectively distributed to the remaining structure.

Membrane Action in Progressive Collapse

The development of a membrane action within the plane of a slab consists of compressive and tensile membrane phases during a typical progressive collapse process. In the compressive phase, along with the downward deformation, the slab attempts to expand in-plane; oppositely, the lateral restraints, provided by columns, produce compressive stresses within the slab. The result of this compressive membrane stress is the considerable enhancement in punching shear strength although the damage continues to expand (Keyvani et al. 2014). Cracks and crushing appear on both slab faces leading to an increase in tensile stresses in the reinforcement, ultimately forming tensile membrane action in the slab. The tensile membrane acts as an alternate load path after the initial column damages, providing an effective load-carrying mechanism to prevent progressive collapse.

The existing experimental results showed that the ultimate load bearing capacities of slabs are much larger than those estimated by the plastic yield-line theory due to the abovementioned membrane actions (Dat and Hai 2013; Yi *et al*. 2014). Therefore, the predictions of the current standards underestimate both punching shear and ultimate loading capacities as these membrane actions, not having been fully quantitatively studied, are neglected. Influences of critical parameters such as material strength, reinforcement ratios, and slab thickness on the formation of membrane actions are yet to be investigated.

EXISTING AND PROPOSED RESEARCH METHODOLOGIES

Progressive collapse occurs unexpectedly and within seconds therefore acquiring first hand data in real time is challenging. The common methodology of in-situ monitoring consequently proves unreliable due to the difficulties associated with dynamic and large deformations. This has led to researchers attempting to simulate the progressive collapse through the use of physical and numerical models for a better understanding of the collapse mechanism and behaviour of the structures. This section presents the existing research methodologies with a focus on the experimental study and numerical simulation of the progressive collapse.

Experimental Investigations of Flat Plate and Slab-Column Structures

To better understand the collapse mechanism of flat plates, several experiments have been conducted on a variety of structure types. Although most experiments are often scaled down due to cost and capacity (e.g. the testing equipment size) restraints, there are exceptional cases. For example, Tian *et al*. (2008) investigated five large-scale isolated RC slab-column connections designed based on the old standards requiring no continuous bottom bars through columns, each tested under a different loading condition. While the experiment was not targeted at identifying the structural behaviours associated with progressive collapse, it revealed that high reinforcement ratios and continuous bottom steel bars increase the strength and stiffness of the connections. A similar conclusion was found by Mirzaei and Sasani (2011) who investigated 26 slab specimens to identify the effects of tensile and integrity reinforcement in post punching shear failure. Ultimately, the strength and stiffness of the connections have been found to rely on the formation of compressive and tensile membrane actions. Yi *et al*. (2014) confirmed these actions by recording concrete and reinforcement strains in the simulation of interior, exterior, and corner column losses.

Qian and Li (2012; 2013a; 2013b) performed a series of experimental tests on RC substructures investigating the progressive collapse resistance. The slab contribution on the ultimate resistance capacity of RC frame structures (Qian and Li 2012) and the influence of drop-panels on the response of RC flat plates (Qian and Li 2013a) were studied. Strengthening of the slab using carbon-fibre-reinforced polymer (CFRP) laminates were also investigated (Qian and Li 2013b). The laminates, being attached either orthogonally or diagonally on the slab surfaces, significantly improved the performance of the RC flat plate structure when compared to the control slab experiments.

The most recent development in RC flat slab research is reported by Russell *et al*. (2015) in investigating the dynamic response on six 2×1 bay slab specimens and one 4×1 bay specimen. It was found that punching shear failure is likely to trigger failure propagation, ultimately leading to a progressive collapse. It was also identified that the load path, after initial damage is sustained, does not necessarily go through the failed column. This interaction was discovered for the first time when an edge column was removed from rectangular specimens, consequently creating an unexpected load path due to the unequal stiffness of the surrounding slab regions.

Numerical Simulations of RC Flat Plates

The use of physical models requires considerable time and cost associated with the manufacturing process and monitoring equipment needed for the test setup. To reduce the constraints on these resources, numerical model are often employed. Moreover, significant safety issues are apparent due to the large deformations that are involved in physical progressive collapse testing, further increasing the desire for numerical modelling.

Kang *et al*. (2009) implemented a set of modelling techniques for simulating the nonlinear behaviour of RC flat plate systems in shake table tests. In their numerical model, the nonlinear behaviour of the slab-column connection was defined and controlled using zero-length link elements including springs and hinges. The adoption of these link elements implied that the slab and columns could be disconnected for the purpose of modelling the separate structural behaviours such as shear and bending. These structural behaviours were further defined by assigning nonlinear mechanical properties to the linking elements. This enabled the exploration of complex structural behaviours including the slab flexural yielding due to unbalanced moment transfer and the loss of slab-to-column moment transfer capacity due to punching shear failure. It is noted that this flat plate model was in a form of a simplified 2D frame where the slabs were modelled by equivalent beams. Therefore, the model was incapable of incorporating the spatial membrane actions. Moreover, the model was only loaded to a limited deformation state and the post punching shear behaviour of RC flat plates in progressive collapse was unable to be evaluated.

Keyvani *et al*. (2014) proposed an alternate modelling method to simulate the behaviour of a slab-column joint with emphasis on the post punching behaviour. The slab was modelled using shell elements whilst the reinforcement was explicitly modelled by beam elements. By means of deactivating the concrete elements through decreasing their stiffness after punching shear failure, the post punching response of the continuous reinforcement could be studied.

Liu *et al*. (2013; 2015) proposed a macro numerical model for progressive collapse analysis of RC flat plate structures. In their model, the region of the slab-column joint was isolated from the remaining slab and the two were linked through connector beam elements. This is because the shell elements alone cannot truly reflect the complex structural behaviour at the slab-column regions. The use of shell elements for modelling the steel bars into smeared reinforcement layers in addition to the definition of the nonlinear responses of the connector beam elements allowed membrane actions and punching shear failure to be investigated.

Xue *et al*. (2014) proposed a spring connection model based on the modelling techniques discussed above. The spring connection unit included five springs representing different structural behaviours at the slab-column region (Figure 2). These springs allowed the bending, axial and shear behaviours of the concrete to be independent of one another while the flexural and integrity reinforcement springs only allowed for axial deformation. By comparing against the experimental result, this connection unit was found to be able to exhibit the initial slab-column joint stiffness after loading and capture the trend of the force-displacement curve. Additional work was required to improve the modelling accuracy of the structural behaviours of the concrete and the reinforcement using such springs as discrepancies appeared at the large deformation stage.

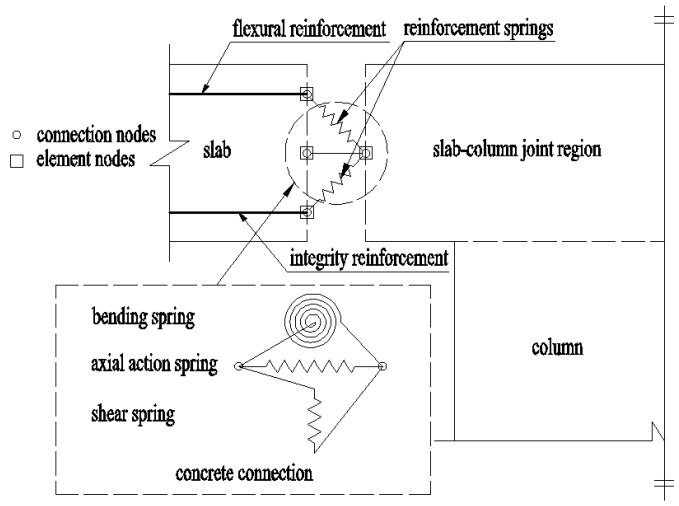

Figure 2 Spring Connection Unit (Xue *et al*. 2014)

DESIGN CONSIDERATIONS AGAINST PROGRESSIVE COLLAPSE

Design guidelines are included in several standards aiming at mitigating progressive collapse which are based on three primary considerations: event control, direct design, and indirect design (Stevens *et al*. 2011; Qian and Li 2013a). The event control method is commonly followed in the engineering management discipline; whereas the direct and indirect design are widely adopted in structural design and implemented through several detailed building strengthening methods discussed below.

Collapse mechanism analyses indicate that structures with higher integrity and redundancy are preferred to resist the progressive collapse. In addition, secondary load-bearing mechanisms are also demanded to confine the damage propagation. Following these two rules, researchers and engineers mitigate the consequences due to progressive collapse by using the following methods: (1) design the elements with higher redundancy and ductility, (2) design the joints with adequate continuity, (3) add alternate load paths, (4) strengthen critical elements, and (5) consider resisting load reversals. Amongst these methods, methods (1) and (2) are able to increase the resistance to progressive collapse by improving the local strength and integrity of the structure, representing the indirect design. In comparison, methods (3), (4), and (5) offer specific threat dependent considerations to mitigate progressive collapse consequences, exemplifying the direct design.

Redundancy, Ductility, and Continuity

Redundancy and ductility facilitate the structures with the capability of resisting collapse (robustness) by providing extra restraints and deformation capacity to the structural elements. They are generally achieved by strengthening the connections and providing structural elements with extra strength. Specifically, load amplification factors and material strength reduction factors are employed in the design process (DoD 2013; GSA 2013). To increase the overall integrity of the structures and effectively redistribute the loads after initial damages, continuity conditions must be satisfied, in particular, in the regions where the horizontal elements (beams and slabs) and the vertical elements (columns and walls) meet. The tie forces check calculation in the guidelines confirms such integrity requirement (DoD 2013, GSA 2013). Additionally, allowing the bottom reinforcement to continuously go through the columns at the joint regions is a typical construction measure to enhance continuity.

Alternate Load Paths

The alternate load paths are the secondary load-bearing mechanism to efficiently redistribute the extra loads to assist the structure to hold positon after the original load path is broken. As the standards (DoD 2013; GSA 2013) specify a rigorous design routine to apply the alternate load path method to structures against progressive collapse, the evaluation of the capability of resisting progressive collapse is able to be simplified as examining the remaining structure losing a critical load-bearing element according to the specified failure criteria (Stevens *et al*. 2011; Valipour and Foster 2010). In addition to the building design, the procedure of “notional removal of elements in a structure” is reasonably practicable in both experimental and numerical research approaches.

Critical Element Strengthening and Load Reversals

Enhancing local resistance approach is put forward to minimise the initial damage which potentially exists according to the occupancy situation (DoD 2013; GSA 2013). In addition to providing elements with standard redundancy and ductility, the capacities of two types of critical elements are required to be distinctively enhanced. Firstly, the elements at special locations (i.e., corner and penultimate edge columns), near openings (i.e., slabs close to elevators), and with special functions (i.e., beams supporting equipment floors) are more likely to experience external impacts or usually bearing extra loads. Secondly, the elements located on the expected alternate load path (i.e., beams above corner and penultimate columns) will undertake extra redistributed loading after the initial damage.

The load reversal typically occurs after the removal of a vertical support element which leads to a change of the load-bearing characteristics (Dat and Hai, 2011). Considering the case of an interior column removal in a RC frame structure, part of the beams and slabs at the removed column location, originally designed to bear negative (hogging) moment, have to carry positive (sagging) moment instead. To worsen the situation, the doubled span length significantly increases this sagging moment, which makes it difficult for the slab to maintain even a small deformation. As such, potential weaknesses are introduced by the absence of the top reinforcement at mid-span and the bottom reinforcement at beam and slab ends due to the compressive actions given by the gravity loads. Accordingly, the continuous steel bars are recommended for both top and bottom reinforcement arrangements.

DISCUSSIONS AND FUTURE WORK

The current trends in the progressive collapse research of RC flat plates are reflected by the increasing efforts of experimental and numerical investigations. Especially, given the execution, cost, and safety considerations, numerical simulation is truly promising. It is also noted that defining the complex punching shear behaviours in slab-column joint regions is rather challenging (Kang *et al*. 2009; Keyvani *et al*. 2014). Specifically, for the spring connection modelling, a set of spring stiffness properties fitted from the existing experimental data would likely to increase the reliability of the numerical model. However, the existing experiments are limited and they vary in load and boundary conditions as well as material properties. In order to make use of these experimental data, new parameters and normalization of variables must be introduced to remove such variations. Alternatively, the spring stiffness could be obtained through analysing an adequately refined numerical 3D slab-column joint models which are capable of capturing the punching shear behaviour. Ultimately, the spring connection modelling would be optimized with enough accuracy to compete the inefficient refined 3D modelling. In addition to the challenge of defining the spring stiffness, the torsional effect, which critically interacts with other structural behaviours in punching shear, must also be considered.

CONCLUSIONS

This work presents a schematic review of the developments of progressive collapse research with an emphasis on RC flat plate structures. Their failure criteria and failure mechanisms are described in some detail. The most recent achievements including both experimental work and numerical simulation, are presented. Several key considerations against progressive collapse as included in the design process are interpreted. Specifically for numerical simulation, a spring connection modelling is discussed yet further improvement is needed. This requires a more precise spring stiffness properties conforming to the experimental data. Furthermore, an additional spring element defining the torsional behaviour at the slab-column joint regions is also expected to be developed.

ABSTRACT

This paper investigates the behaviour of a bio-inspired finite element composite model (that mimics the structure of nacre, the inner layer of molluscan shells) under blast loading. Nacre, which has attracted the attention of researchers over the past few decades, comprises 95% aragonite, brittle voronoi-like polygonal tablets that are joined by an organic matrix and arranged in a brick and mortar type structure. The best attempt made thus far in mimicking such complex geometry involved rebuilding the tablet contours via optical imaging. This method, which practically copies the nacreous structure, offers no control over the geometry, making it difficult, if not impossible to eventually develop composites that mimic nacre. To this end, the finite element model developed herein was constructed using voronoi diagrams and geometric algorithms capable of automatically generating staggered layers of voronoi-like aluminium tablets bonded together by a vinylester adhesive layer. Many studies have led to the belief that the magnificent toughness of nacre is mainly attributed to the inter-platelet adhesive bonds. Results obtained from the finite element analysis show that this is indeed true, and it is imperative that the adhesive bond exhibits adequate toughness in order to be able to spread damage across the entire composite, thereby delaying localised failure.

Nacre, composite panel, blast loading, voronoi structure, bio-inspired structure.

INTRODUCTION

Biological materials, meta-materials, woven fabrics, nano-polymers, composite sandwich panels and many others have recently been investigated by structural research engineers because of their unmatched mechanical performance over traditional engineering materials (Tran 2014; Ghazlan 2015; Imbalzano 2015; Nguyen 2015; Yang 2015). Nacre, the inner layer of mollusc shells, stands out among them as the toughest, boasting a fracture toughness of up to 1240J/m^2 (Barthelat 2007). Specifically, the nacreous structure comprises 95% aragonite, in brittle ceramic tablets (or bricks), which are joined by an organic matrix (mortar) and arranged in a bricks and mortar type structure. In particular, the most striking attribute of nacre is its toughness, which is 3000 times greater than its bulk constituent (brittle aragonite).

Much effort has been devoted to characterising the mechanical behaviour of this magnificent organism in order to understand the mechanisms responsible for its superior toughness. In fact, many have observed that the nacreous tablets are not flat, and that diffusive sliding between the tablets is the key mechanism responsible for nacre's unmatched toughness (Ghazlan 2015). Specifically, when the organic matrix deforms in its plastic state, the aragonite tablets begin to slide on one another. Because the tablets are not flat, a hardening effect is activated through the interaction between their wavy surfaces. This has the effect of spreading the tablet sliding mechanism across the entire volume, thereby increasing the energy absorbing capacity of the system and delaying localised failure.

From this mechanism, one can intuitively deduce that the contact area between the tablets is an important parameter in the design of a nacre-mimicking composite system. To this end, Wei et al (2012) and Dutta et al (2013) developed analytical models of a rectangular unit cell cut out from the nacreous structure, to quantify the optimal overlapping length of nacre under planar static and dynamic tensile loading, respectively. By maximising the strain energy density of the unit cell and minimising the shear stress in the matrix, they we able to obtain optimal overlapping lengths that were similar to that found in nacre. Although these results give some insight into the nacre's toughening mechanisms, they are inconclusive when it comes to structural applications because transverse loading is the dominant imposed action. Furthermore, the simplified geometry of the unit cell is inaccurate when considering the complex nacreous tablet arrangement, as the tablets are arbitrarily shaped polygons.

Barthelat et al (2007) found that nacre exhibits a voronoi-like tablet architecture through optical imaging of a red abalone specimen. They reconstructed the tablet contours and input them into a numerical model. This method, which practically copies the structure of nacre offers no control over the geometry, which becomes infeasible in the development of a nacre-mimicking composite.

The objective of this research is to develop a finite element model of a multi-layered composite structure that mimics the geometric structure of nacre. The model will be applied to predict the performance of the composite under blast loading until catastrophic failure. In this work, we also develop geometric algorithms for generating the components in each layer of this composite structure, namely the polygonal nacreous voronoi tablets and the cohesive elements to bond them together.

FINITE ELEMENT MODEL

Construction of the nacre-mimicking geometry

Voronoi diagrams, which are well-known in computational geometry, are employed in this work to construct the geometry of the nacre-mimicking finite element model. Briefly, a voronoi diagram comprises of sites (or points) as shown in Figure 1, where every point inside the polygon enclosing the site is closest to that site. Mathematically, this can be represented by the following equation:

$$R_k = \{x \in X | d(x, P_k) \leq d(x, P_j) \forall j \neq k\}$$

Where R_k is the set of all points in the voronoi diagram X such that the distance $d(x, P_k)$ between each point x and a site P_k is less than or equal to the distance $d(x, P_j)$ between x and any other site P_j. The simplest possible configuration for a voronoi diagram is shown below in Figure 1a, where the sites are arranged in a grid to form square voronoi regions. By staggering the sites, the voronoi regions become hexagons (Figure 1b).

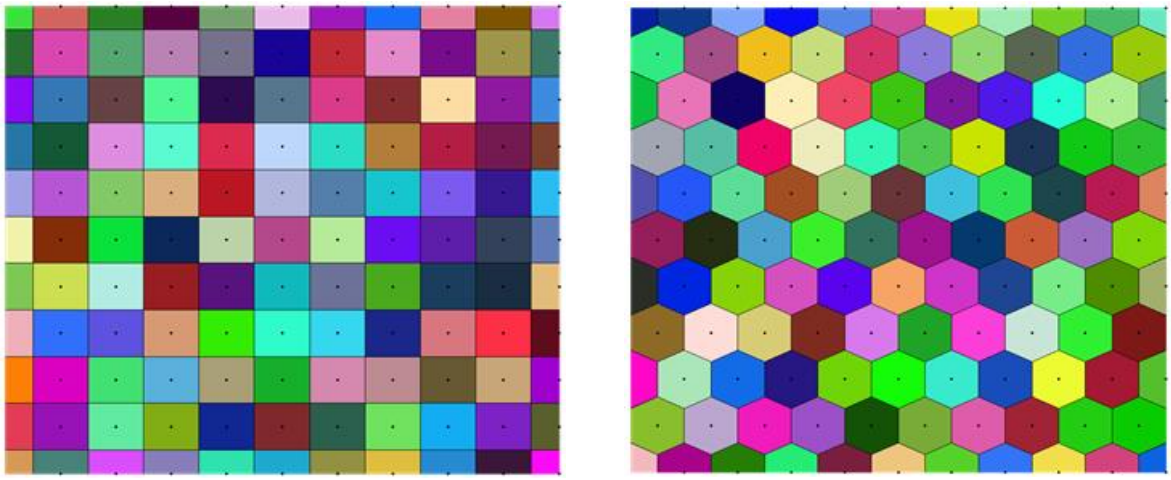

Figure 1 (a) Grid arrangement of voronoi sites yielding square voronoi regions; and (b) staggered arrangement of voronoi sites yielding hexagonal voronoi regions.

It can be observed from Figure 1 that the polygons at the boundary of the voronoi diagram are cut off. If this were not the case, they would extend infinitely, as the voronoi diagram has no boundary. To address this limitation, rectangular cropping is defined as an imaginary boundary, and the polygons are then cut to lie inside this region (Figure 2).

The abovementioned procedure was illustrated for a simple case, where the voronoi polygons are squares or hexagons. This can be extended to a more general case where the polygons become arbitrary regions as illustrated in Figure 3. The geometry of these regions can be manipulated by placing an imaginary circle around each site and allowing the site to move randomly within this circle according to equation 1, which dictates its position (x, y) in polar coordinates:

$$x = x_0 + rcos(\theta);\ y = y_0 + rsin(\theta) \quad (1)$$

Where: $(x_0 y_0)$ is the reference position of the site i.e. in a grid formation (Figure 1); r is a random value in the range $[0, R]$, where R is the chosen radius of the circle and; θ is a random angle in the range $[0, 2\pi]$. The radius R

is chosen as a function of the inter-layer overlapping area found in nacre, which is one-third of the area of the tablets on average. The resulting nacreous layer is shown in Figure 2a.

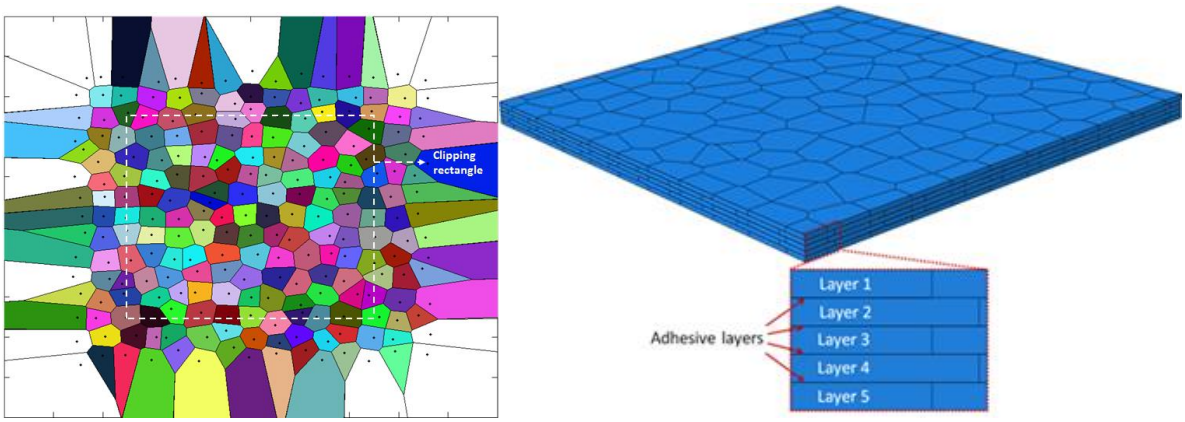

Figure 2 a) An example of a general voronoi diagram resembling a nacreous layer; and b) Assembled model mimicking nare's structural architecture, with nacreous layers bonded together by zero-thickness adhesive layers.

The next step involved the automatic insertion of zero-thickness cohesive elements between the grains of the platelets. To achieve this, the geometry of the nacreous layer illustrated in Figure 2a was imported into the finite element program ABAQUS and meshed. The mesh was then operated on directly to insert the cohesive elements between the voronoi polygons systematically. A simple example of this procedure is illustrated in Figure 3. Once the polygons were all connected by cohesive elements, they were extruded to form a three-dimensional nacrous layer. It is important to note that the node ordering required by the finite element (FE) program (ABAQUS in this case) is adhered to i.e. the stacked orientation of the cohesive elements is used to distinguish axial and shear behaviour. The above process is then repeated to generate five staggered layers, as illustrated by the brick and mortar arrangement in Figure 2b. The nacreous layers are then tied together by adhesive layers of negligible thickness, forming the composite model.

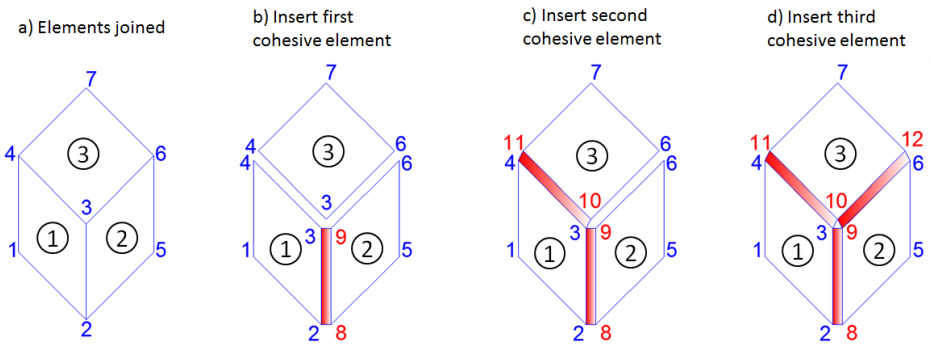

Figure 3 Simple process of cohesive element insertion at a junction formed by three elements.

MATERIAL MODEL

Cohesive model for composite interface

Delamination is an important failure mode in composite materials subjected to transverse loads. It can cause a significant reduction in the compressive load-carrying capacity of a structure. The debonding behaviour of the composite can be simulated by the Cohesive Zone Model (CZM).

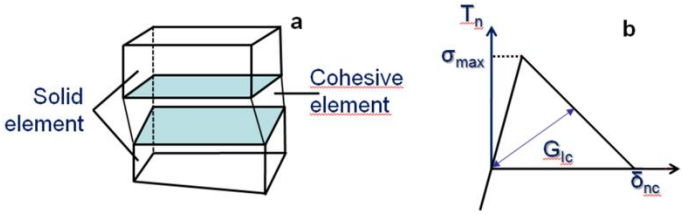

Figure 4 (a) 3D Eight-node cohesive element; (b) Rate-independent bilinear cohesive model.

This research employed a bilinear cohesive model illustrated in Figure 4b. The cohesive elements with finite thickness connect two volumetric elements as shown in Figure 4a with traction-separation laws, which relate the cohesive traction vectors T={t_n, t_s, t_t} and the displacement jump $\boldsymbol{\delta}$ ={δ_n, δ_s, δ_t}, where the subscripts n, s and t, respectively, denote the normal and tangential components. We adopt a simple bilinear cohesive law for damage initiation:

$$\left\{\frac{\boldsymbol{t_n}}{\boldsymbol{t_n^0}}\right\}^2 + \left\{\frac{\boldsymbol{t_s}}{\boldsymbol{t_s^0}}\right\}^2 + \left\{\frac{\boldsymbol{t_t}}{\boldsymbol{t_t^0}}\right\}^2 = \mathbf{1} \tag{2}$$

Where $\boldsymbol{t_n^0, t_s^0, t_t^0}$ represent the peak values of the nominal stress when the deformation is either purely normal to the interface, or purely in the first or the second shear direction, respectively. The power law form was adopted to describe the rate of stiffness degradation:

$$\left\{\frac{\boldsymbol{G_n}}{\boldsymbol{G_n^C}}\right\}^2 + \left\{\frac{\mathbf{G_s}}{\boldsymbol{G_s^C}}\right\}^2 + \left\{\frac{\mathbf{G_t}}{\boldsymbol{G_t^C}}\right\}^2 = \mathbf{1} \tag{3}$$

Where $\boldsymbol{G_n^C, G_s^C, G_t^C}$ refer to the fracture energy required to cause failure in the normal and shear directions, respectively. The cohesive material model adopted in this work is representative of vinylester resin and its properties are tabulated below.

Table 1 Vinylester cohesive material model

t_n^0, t_s^0, t_t^0	80 MPa
G_n^C, G_s^C, G_t^C	$1\,J/m^2$
ρ	$1850\,kg/m^3$
E_{nn}	4 GPa
E_{ss}, E_{tt}	1.5 GPa

- **Rate-dependent model for the nacreous tablets**

A rate-dependent material model was adopted to simulate the behaviour of the polygonal tablets. The Johnson-Cook constitutive law (for the Von Mises flow stress) for ductile metals (Johnson and Cook 1983) was utilised to predict this behaviour as follows:

$$\sigma = [A + B\epsilon^n][1 + Cln\dot{\epsilon}^*][1 - T^{*m}] \tag{4}$$

Where A represents the yield stress; $\boldsymbol{\epsilon}$ is the equivalent plastic strain; B and n account for the effects of strain hardening; $\dot{\boldsymbol{\epsilon}}^* = \dot{\boldsymbol{\epsilon}}/\dot{\boldsymbol{\epsilon}}_\mathbf{0}$ is the dimensionless strain rate for the reference strain rate $\dot{\boldsymbol{\epsilon}}_\mathbf{0} = \mathbf{0.001}\boldsymbol{s^{-1}}$; the constant C is obtained from experiment (tension, torsion, etc.); and the temperature $\boldsymbol{T^{*m}}$ is ignored, assuming isothermal conditions. The material employed in this work is Aluminium AA5083-H116, with properties listed in Table 2.

Table 2 Aluminium AA5083-H116 material model

ρ	$2750\ kg/m^3$
Elastic	
E	70 GPa
ν	0.3
Plastic	
A	215 MPa
B	280 MPa
n	0.404
m	0.859
C	0.0085
$\dot{\varepsilon}_0$	$0.001\ s^{-1}$

- **Blast model**

The Conventional Weapon Effects (CONWEP) card in ABAQUS was used to simulate blast loading on the front face of the nacreous composite, which is equivalent to a 0.15 kg TNT charge at a standoff distance of 0.5 m. The peak incident overpressure for this case is approximately 15 MPa, which is representative of a close range detonation.

RESULTS

Figure 5 illustrates the damage contours in the adhesive layer at the back face of the nacreous composite. Initation of damage occurred at t=1.2 ms, whilst the onset of failure occurred at t=1.5 ms. It can be observed that damage is nucleating and propagating out from the center of the adhesive layer until catastrophic failure occurs at t=2 ms. This is due to the low fracture toughness of the vinylester adhesive, which is two to three orders of magnitude smaller than that of nacre. Specifically, premature failure of the adhesive does not allow for the tablet sliding mechanism to be activated over the volume of the composite, leading to localised failure.

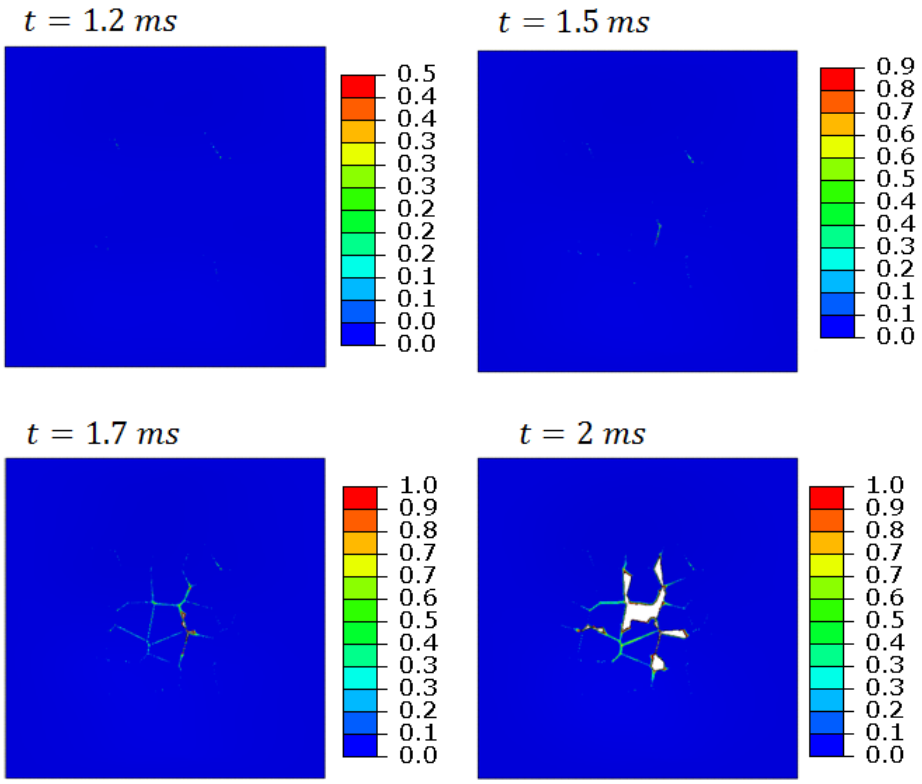

Figure 5 Damage contours in the adhesive layer near the back face of the nacreous composite.

The Von Mises stress distributions of a monolithic plate (of equal areal mass) are compared with the nacreous composite. The stress patterns are in close agreement between both models up to t=1.5 ms. This means that the

nacreous composite was able to spread out its deformation mechanism from the region of damage initiation since the stiffness of the adhesive layer did not degrade significantly. At the onset of failure (t=1.7 ms), the stiffness of the adhesive degrades entirely in the central region leading to stress concentrations in the tablets as there is no hardening mechanisms operating to delayed localised failure. This is evident in the increasing stress gradient observed from t=1.7 ms to t=2 ms in Figure 6 below.

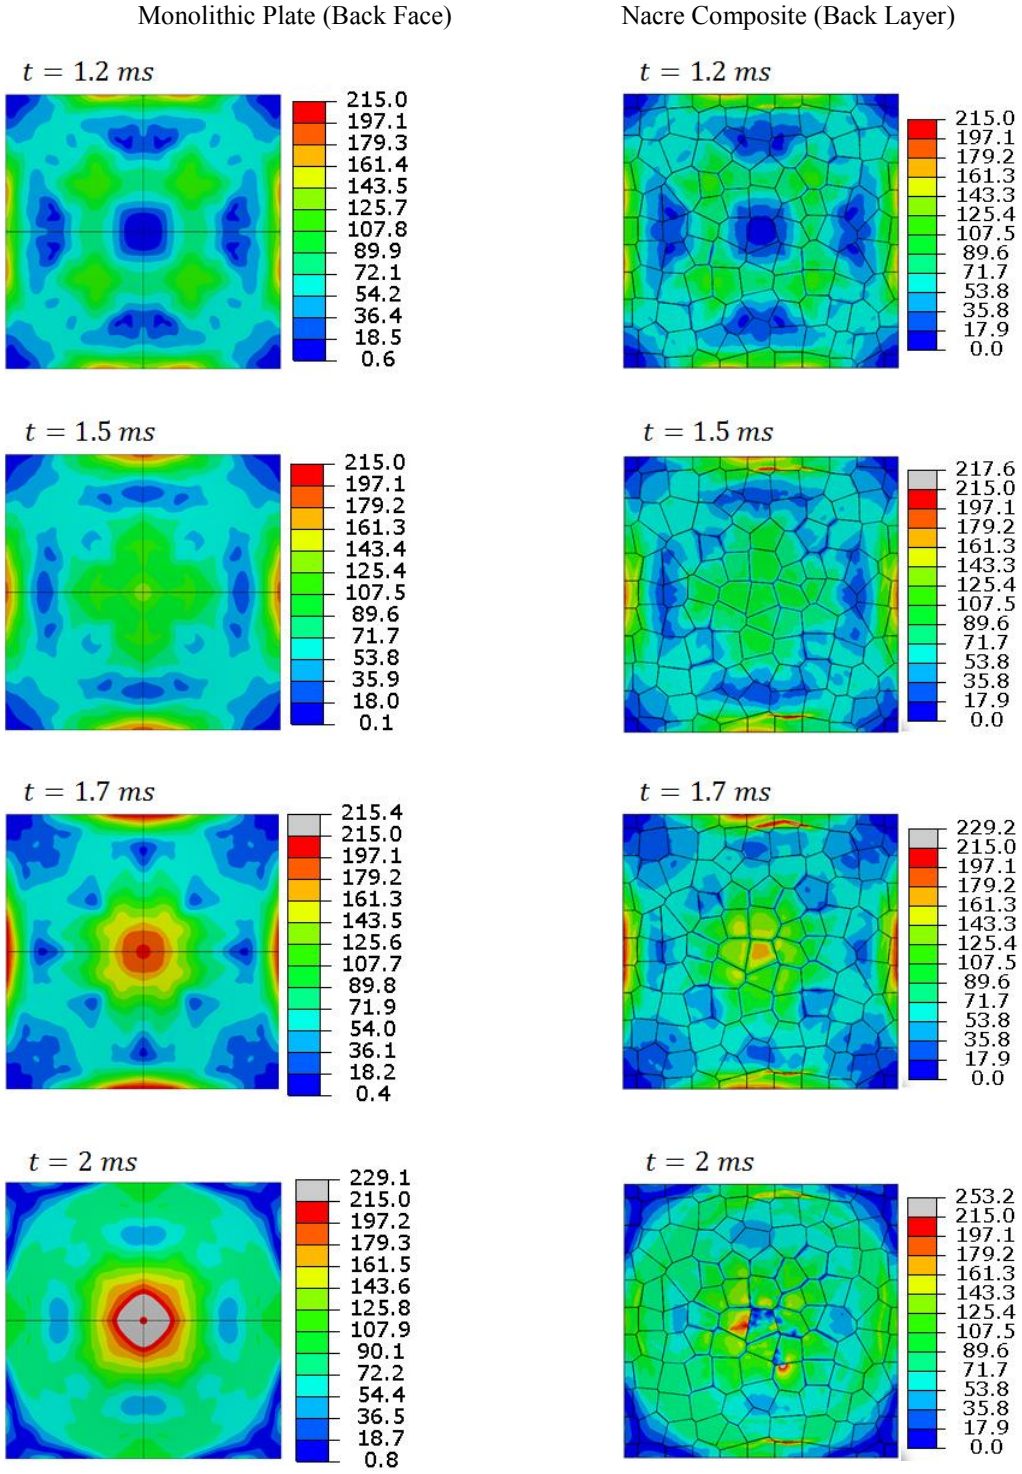

Figure 6 Von Mises stress comparison between the back face of the monolithic plate (left) and the back layer of the nacre composite (right). The cases where the damage initiated in the nacre composite (t=1.2 ms) to the runtime (t=2 ms) are shown. Both models are of equal areal mass

The plots for several components of energy are compared between the monolithic plate and the nacre composite in Figure 7. A close correlation between the kinetic and internal energies can be observed. The main mechanism of energy dissipation that operates in the nacre composite is damage. This is significant because a region of localised stress forms in the tablets, such that the plastic deformation mechanism is not spread out among the tablets (see Figure 6). This behaviour can be correlated to the minor plastic dissipation energy in both models observed in Figure 7. The monolithic plate dissipates a negligible amount of energy via plastic deformation, and no damage energy dissipation occurs at all. This is because the majority of the energy due to the blast load is absorbed by the monolithic plate in the form of recoverable strain energy.

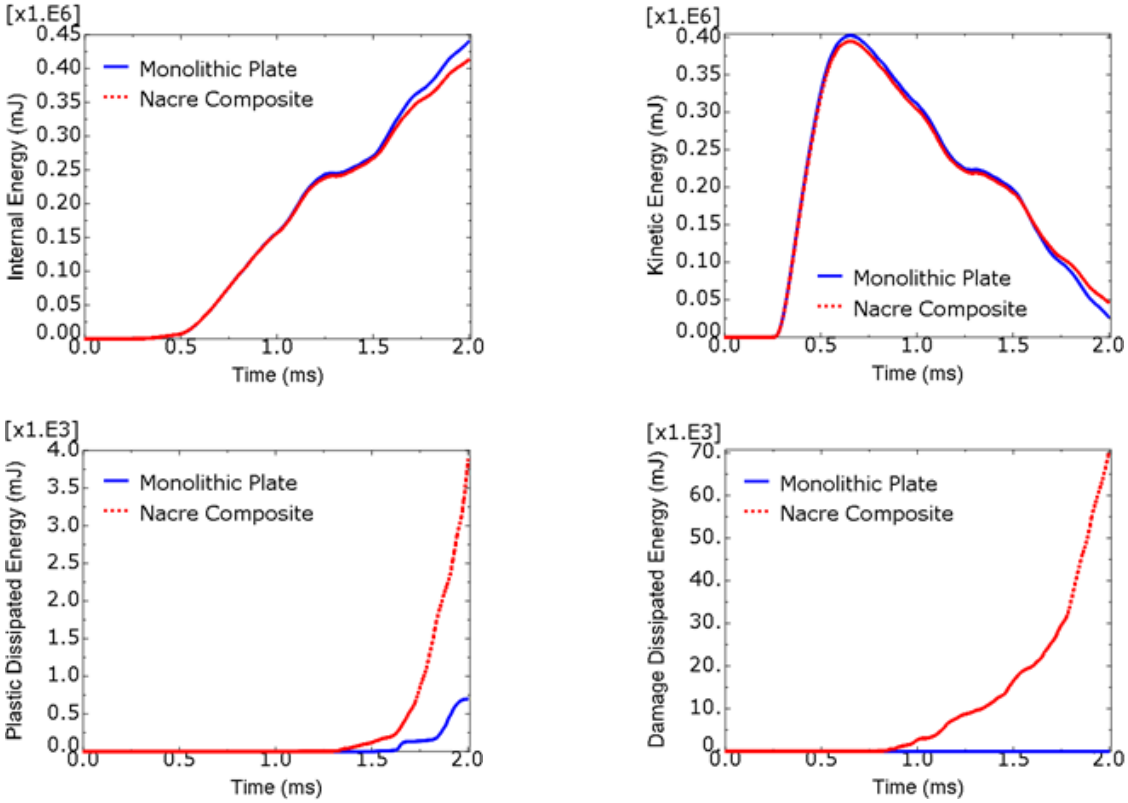

Figure 7 Energy comparisons between the monolithic plate and the nacre composite

The transverse displacements and velocities at the back face of the monolithic plate and the nacre composite are compared in Figure 8. A significant difference between the velocities of both models can be observed at the onset of failure (t=1.7 ms). The displacements between both models show close agreement. Contrary to the monolithic plate, the nacre composite cannot recover back to its equilibrium position due to localised failure of the adhesive. Therefore, the importance of the toughness of the adhesive layer cannot be overstated.

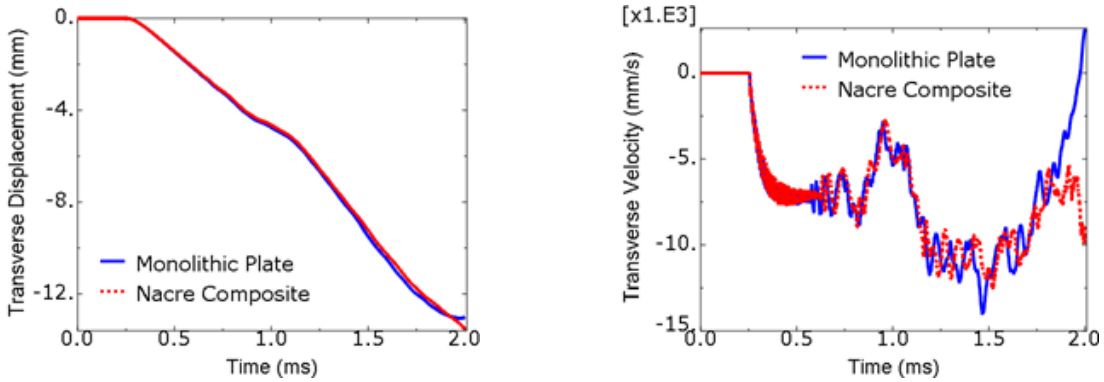

Figure 8 Transverse displacement (left) and velocity (right) comparisons between the monolithic plate and the nacre composite

CONCLUSION

A nacre-mimicking composite model was subjected to blast loading and its mechanical behaviour was compared to a monolithic plate of equal areal mass. Similar behaviour was observed between both models until the onset of failure, where the stiffness of the nacre composite degraded entirely. This is attributed to the low toughness of the adhesive material bonding the nacreous layers together, which leads to stress localisations that inhibit the spread of the deformation mechanism across the volume of the composite. Further research is required to verify this, and to investigate the influence of the interactions between the tablet surfaces of wavy geometries on the energy absorption capacity of the composite, by introducing additional toughness to the adhesive layer.

ABSTRACT

Recent bridge collapses have raised an awareness of, and a concern for, the safety and robustness of bridges subjected to blast loading scenarios. The incident pressure generated by the explosion can cause severe structural damage and a loss of critical structural members, resulting in partial collapse of the bridge. Previously, most relevant research effort has been devoted to understanding the response of buildings under blast loading and to develop guidelines to increase the resistance of such structures, while relatively little research attention has been focused on bridge structures. Recent advancements in numerical methods have enabled the viable and cost-effective simulation of complicated blast scenarios, and hence these methods provide a useful reference for safeguarding design and assessment of critical infrastructure. To reduce the computational costs, previous studies on long span bridges under blast loads typically take advantage of sub-structuring techniques, in which only part of the structure is modelled. However, such oversimplifications can lead to erroneous results. Accordingly, this study is an attempt to simulate the dynamic response of an entire cable-stayed bridge subjected to blast loading based on best practice techniques obtained from the literature. The response of a steel bridge, designed according to the minimum requirements of the Australian Standard AS5100, is investigated when subjected to blast loads ranging from small to large explosions at different positions above the deck using numerical simulations. In addition, the potential effects of blast loads on different structural components (*i.e.* the deck and pylons) are discussed and possible blast mitigation strategies such as the application of FRP and optimization of the geometry of the pylons are investigated.

INTRODUCTION

Recent bridge collapses have raised an awareness of, and a concern for, the safety and robustness of bridges subjected to blast loading scenarios. The incident pressure generated by the explosion can cause severe structural damage and a loss of critical structural members, resulting in partial collapse of the bridge. The design provisions for blast resistant bridges are limited due to inadequate knowledge of the local and global dynamic response of the bridge components (i.e. piers, deck and cables) subjected to blast loading scenarios. Furthermore, the existing design guides for blast-resistant bridges are limited to particular structural components (NCHRP 2010).

Bridge structures are typically more vulnerable to extreme loading scenarios than buildings because bridges have less structural redundancy compared to buildings. Thus, in the case of failure of any primary structural members in bridges, redistribution of the applied load through an alternative load path to prevent potential progressive collapse is almost impossible. For example, failure of the pylon in cable-stayed bridges can cause complete collapse of the entire bridge. The loss of a critical bridge or tunnel can potentially lead to severe casualties and billions of dollars as direct reconstruction expenses. Furthermore, the socioeconomic costs involved in such a collapse can double the cost of constructing a new long span bridge (FHWA 2003).

To design bridges to withstand blast loads, an engineering understanding of blast wave propagation and its effects on structures is needed. Numerical techniques can be used to model the explosion and structure, so as to study the interaction between them. Recent advancements in numerical methods have enabled engineers to simulate complicated blast scenarios in a viable, efficient and cost-effective way and subsequently to provide useful reference data for the safeguarding design of critical infrastructures. Accordingly, computer simulations have been used by different researchers to capture the failure mode and dynamic response of cable stayed bridges subjected to hypothetical blast scenarios (Son and Lee 2011, Tang and Hao 2010, Hao and Tang 2010).

The finite element (FE) package MD Nastran was used by Son and Lee (2011) to evaluate the response of a hollow steel box pylon of a cable-stayed bridge subjected to blast loads. The interaction between the air blast and a part of cable stayed bridge pylon was captured by an Arbitrary Lagrangian Eulerian method (ALE). In Son and Lee's FE model, the cables were omitted and only the corresponding forces in the cables were applied on the model and assumed to be constant throughout the analysis. The FE predictions showed that the P-Δ effect can cause significant instability in the hollow steel box pylons subjected to a blast scenario. Using a concrete-filled steel section in the vulnerable part of the pylon demonstrated superior performance under blast loads.

Tang and Hao (2010) and Hao and Tang (2010) used the FE package LS-DYNA to study the numerical simulation of a fixed-base cable-stayed bridge under blast loading with damage prediction and possible retrofitting strategies. The simulation contained most important bridge components such as the pier, tower, back span and steel-concrete composite main span, but investigated individually. The failure of the bridge was predominantly due to compressive crushing and spalling of concrete materials with reinforcing bar and steel plate failure. The damage area of each bridge component was significant, but they are still localized, however this could cause bridge to lose its stability. Progressive collapse analysis of the bridge structure uncoupled with blast loading also showed failure of the main span was unlikely and back-span destruction did not extend through entire structure. Moreover the application of CFRP strengthening on the deck is ineffective even though strengthening does reduce the effects.

To reduce the computational costs, the previous studies typically take advantage of a sub-structuring technique, in which only part of the structure is modelled. However, such oversimplifications can lead to erroneous results. Hence, the dynamic response of an entire cable-stayed bridge with a truss deck subjected to blast was studied by Deng and Jin (2009) and it was concluded that the explosion can lead to localised destruction of the deck in the vicinity of the detonation. However, the dynamic response of the entire truss deck was insignificant, mainly because the truss elements were not affected by the air blast pressure.

It must be noted that the interaction between any structural components could affect the response of the entire structure in the event of blast explosion. Assessing the vulnerability of bridge individual elements cannot show the probable progressive collapse of entire bridge structure, while it is the first step to understand the extent of the damage. Designers also need to consider the post-blast behaviour of the damaged structure under gravity loads, and the instability it could cause. Consequently, it is of importance that the blast resistance of bridges, in particular those having a long span, be studied and necessary mitigation implemented for safety protection in the future. To this end, the current study intends to simulate the dynamic response of an entire steel cable-stayed bridge subjected to close-range detonation using the LS-DYNA (Hallquist 2014) explicit finite element package. The cable-stayed bridge was designed according to the minimum requirements of Australian standards (AS5100 2004) and analysed under dead, traffic and blast loads at different locations close to the pylon. The results of the FE models are used to assess the performance of bridge pylons and cables as well as the entire bridge exposed to an air blast.

Furthermore, the potential effects of blast loads on different structural components (*i.e.* deck and pylons) are discussed and values of the demand-to-capacity ratio (DCR) at different sections along the pylon computed to establish a damage criterion. The maximum strain in addition to the DCR values are used to evaluate the performance of a proposed octagonal hollow section under blast loads in comparison to the existing rectangular steel sections. In the current study, the DCR is defined as

$$\mathrm{DCR} = \left| \sigma_{\max} / \sigma_y \right|, \tag{1}$$

where $\sigma_{\max}$ is the maximum stress in the section due to design load or blast loads and σ_y is the yield stress. In blast load cases strain rate is taken into account in the calculation of σ_y at each time. A DCR value exceeding unity indicates that the material is in plastic region (material non-linearity).

DESCRIPTION OF MODELS AND ANALYSIS TECHNIQUES

Bridge details

For security reasons, a hypothetical cable stayed steel bridge which is shown in Figure 1 was designed according to minimum requirements of the Australian bridge standard AS5100 (2004) to avoid publishing vulnerabilities for a specific bridge. The proposed bridge consists of three spans, which are 227.5 m, 580 m, and 227.5 m long.

The steel orthotropic box deck is 28 m wide and 2.0 m deep which provides 6 traffic lanes and 2 walkways and designed as a closed hexagon multi-cell box. A 25 mm thick plate was used as top and bottom flange of deck. The longitudinal stiffeners are 400 mm high and spaced at 700 mm for both flanges. Intermediate stiffeners are used for 20 mm web plates at 4 metre spacing. The deck is supported on transverse diaphragms to prevent premature excessive distortional deformation under torsional loading every 10 m. The distance between the diaphragms is reduced to 5 m at both ends of the deck, close to the pylon and at mid-span. A cross-sectional view of the deck is shown in Figure 2. The bridge deck is connected to two A-shaped 136 m tall steel box pylons by 112 cables (Figure 3). A transverse steel box girder connects the pylon legs and the thickness of plates and spacing of the stiffeners inside the pylon box is chosen in such a way that a compact section is provided. The cross-sectional view of the pylon is shown in Figure 4. The cables consist of Grade 270 strands with an ultimate stress of 1860 MPa. The first four cables adjacent to the end supports of the deck are 5 m apart and the other cables are 20 m apart along the bridge deck. The cable area varies from 23,600 mm^2 to 7,700 mm^2 and initial axial post-tensioning varies from 12 MN to 5 MN to provide minimum deflection on deck in respect to permanent loads.

All important components that would have an influence on the bridge response are included such as the diaphragm's stiffeners and manhole. Furthermore, different mesh sizes were used in the FE model to achieve both accuracy and computational efficiency. For example, a finer mesh was used for the zones in the vicinity of the explosion as presented in Figure 5 and Figure 6. The nodes at the base of the pylons are constrained as being fixed in all DOFs while pin support in one end of deck and roller support at the other end were implemented in model.

Material model and strain rate effects

The steel material used in the deck and pylons is assumed to have elasto-plastic hardening and strain-rate dependency with quadrilateral, fully integrated shell elements. Such an element provides more accurate results and requires a relatively small amount of computation time (Hallquist 2014). The adequacy of material model *MAT_ PIECEWISE_LINEAR_PLASTICITY (MAT_24) in LS-DYNA for modelling the nonlinear behaviour of steel elements subjected to high strain rate loading has been demonstrated through several studies (Jama *et al*. 2009, Hashemi and Bradford 2014). Also, this material model takes advantage of a maximum strain criterion for capturing the onset of failure. The properties of the structural materials are tabulated in Table 1.

Table 1 Material properties

		E	σ_y	σ_u	ε_{max}	A*	I_{yy}*	I_{xx}*	Initial Force
		GPa	MPa	MPa		m^2	m^4	m^4	MN
Deck		200	350	450	0.15	2.735	2.047	194.122	-
Pylon		200	350	450	0.15	2.532	17.431	13.653	-
Cables	Type1	200		1860	0.03	0.0236			12

	Type3	200		1860	0.03	0.0077			5

* The geometrical properties of the pylon cross section were calculated for only one leg.

The yield and ultimate strengths of steel increase under high strain rate while the maximum strain and modulus of elasticity show no specific change to those obtained from static loads. The current study employs the dynamic increase factor to account for the material strength enhancement with strain rate effect for steel, based on the Cowper-Symonds (CS) equation given by

$$\mathrm{DIF_s} = 1 + \left(\dot{\varepsilon}/C\right)^{1/p}, \tag{2}$$

where $\dot{\varepsilon}$ is the strain rate and C and p are Cowper-Symonds constants. For mild steel, Cowper and Symonds (1957) suggested 40.4 s^{-1} and 5 for C and p respectively, while Paik and Thayamballi (2003) suggested values of 3200 s^{-1} and 5 as the CS constants to consider the strain rate on the behaviour of high-strength steel.

The CABLE_DISCRETE_BEAM (MAT_71) material model was used for the elastic cables on the bridge. This material model permits elastic cables to be realistically modelled; thus, no force will develop in compression (Hallquist 2014). The initial post-tensioning forces in cables are given in Table 1. In this study, each component of the bridge structure was given an appropriate material constitutive model.

Gravity and Traffic Loads

The applied loads on the bridge are assumed as gravity load included self-weight (DL) and surfacing (SDL) plus the traffic load (TL), S1600, according to (AS5100 2004). The self-weight is calculated automatically in the software when the keyword *BODY_Z is activated. To consider the connections and weld weight, the deck weight was increased by 15%. 150 mm of insulant and asphalt, as a final coat on the deck, was assumed and applied as a superimposed dead load. Traffic loads were converted to equivalent pressure so they can be easily applied to the shells to minimise the modelling complexity. Two different traffic load cases (TLC) were

considered and denoted TLC1 and TLC2. In TLC1, the traffic loads are assumed to be distributed on the entire bridge deck, while in TLC2, traffic loads are applied only on the main span. Even though both cases were modelled and analysed, only that which gives the severer response is presented herein.

The AASHTO (2012) suggests the load factor for live load γ_{EQ}, shall be determined on a project-specific basis for Extreme Event I and proposed γ_{EQ} = 0.50 is reasonable for a wide range of values of average daily truck traffic in Extreme Event II. Consequently, 50% of the traffic loads (TL) was applied to the model in combination to blast loads.

Blast Scenarios and Explosives weight

Three explosive weights, *viz*. 01W (small), 04W (medium) and 10W (large) were considered in this study. W is the equivalent TNT weight index that is not specified in this study due to security reasons. Four different locations for the explosives were considered to produce the most critical close-range blast loads on pylon (Figure 7). The location of the explosives in the three scenarios was above the deck and in one of the scenarios (*i.e*. BS04), the explosive was placed below the deck and one metre away from the pylon's base. Above the deck explosions were at the possible closest distance to pylon's left leg (BS01), one metre from the middle of the cross-section of the deck at pylon's centre line (BS02) and adjacent to the first cable anchorage zone in the back span (BS03). The following combination of actions is used to evaluate the bridge response under the blast loads (BL):

$$Q = 1.0\times DL+1.4\times SDL+0.5\times TL+1.0\times BL. \quad (3)$$

The *BLAST_ENHANCED command is employed to apply the air blast pressure on the facets defined with the keyword *BLAST_SEGMENT_SET. The normal of each segment should point away from the structure and towards the charge. Additional segments are defined for the bottom flange and the components inside the deck girder to ensure that the extent of damage is captured by the model, in case that the top (surface) flange of the deck is ruptured. In scenario BS04, the combined effect of air blast pressure and ground shock combination have been taken into account.

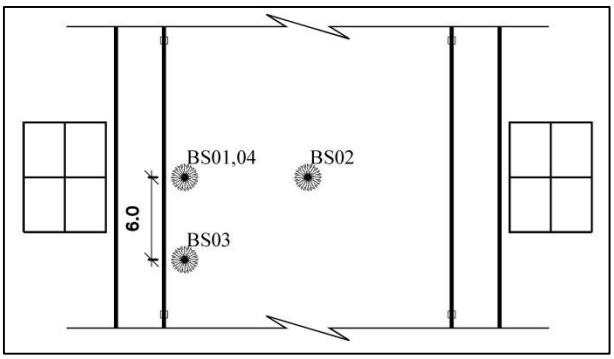

Figure 7 Different blast scenarios (BS)

Blast pressure verification

Before any conclusions regarding the models in this study can be arrived at, the blast modelling and its applied reflected pressure on different parts of the bridge need to be verified. Since a limited amount of experimental data is available in literature, The US Army manuals (UFC-3-340-02 2008) blast pressure prediction which are based on published and unpublished tests, are used to compare the results of finite element analysis herein. For this reason the arrival time and calculated reflected pressures on different elements of the pylon for different explosive weights were obtained and are compared to those in the UFC 3-340-02. Because figure 2-7 in UFC 3-340-02 gives only the normal peak reflected pressures and the normal reflected impulses, only normal values are included in

Figure 8 and

Figure 9. The arrival time is quite similar while the peak reflected pressure is about 15% less than the peak reflected pressure from UFC 3-340-02. According to the verification through the reflected pressure at different points in Figure 9, the calculated blast pressure on the structure is reliable.

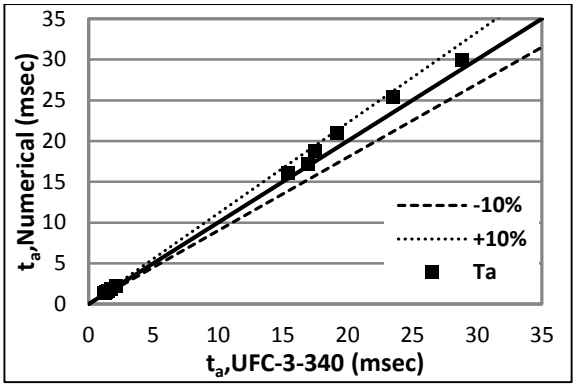

Figure 8 Arrival time

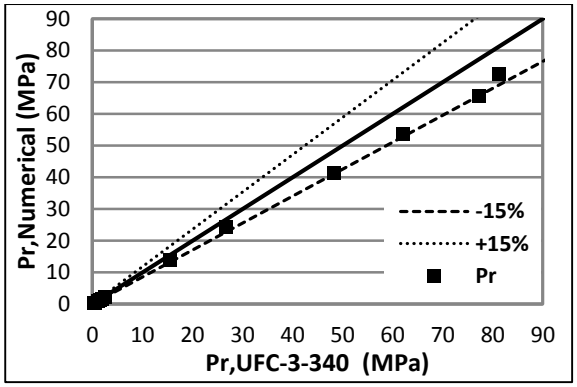

Figure 9 Reflected pressure

RESULTS AND DISCUSSIONS

Dynamic Response of Pylon

When the detonation occurs, the shock front generated from the blast is transferred into the air and travels with high speed until it strikes an object. This causes the wave speed becomes zero and leads to reflected pressure on the object. This reflection is dependent on the geometry, density, blast shock wave speed and arrival time, and other dynamic properties of the object (Son and Lee 2011).

In the scenario with 01W explosive on the deck, the shock causes small localised damage to top flange of the deck, however, no specific deformation is observed at Closer Leg (CL) of the Closer Pylon (CP) to the detonation point. Overall, the bridge remains almost intact under 01W explosive meaning that no repair is required apart from a small area on the deck right under the explosion. No plastic deformation is observed in the structural components and the oscillation of the bridge is damped after a few seconds and the pylons and deck return back to their initial state before the blast. Accordingly, this section focuses more on the bridge response to medium (04W) and large (10W) explosive charges.

The extent of damage in the deck and pylon due to blast loads at different locations above the deck and near the pylon for explosive weights 04W and 10W are shown in Figure 10. The maximum deformation in the pylon for the above the deck explosions occurred in the BS01 scenario, when the explosive is placed in the centre line of the pylon at one side of the deck. The closest face of the pylon to the explosion experienced a large relative deflection as much as 400 mm in 10W detonation which indicates a 12 degree of rotation at the corner support of the plate. Moreover, longitudinal stiffeners and diaphragms attached to that face are affected by the deflection. Moving the position of the explosive along the cross-section (BS02) or along the traffic lanes (BS03) increases the standoff distance as well as the incident angle. The blast pressure in BS03 had minimal impact on the pylon, but its effect on the deck was more critical. According to the FE predictions, in scenario BS03, the cable anchorage zone close to the explosion experienced damage that caused cable detachment even with medium explosive size. In the scenarios BS04-10W, the CP underwent extensive damage. In particular, the explosion caused significant rupture of steel plates in the CP at the level of detonation (Figure 10-h). Crushed zone estimated about 8.5 m height and 8 m wide.

The maximum demand over maximum capacity ratio of the cables connected to the CP on the right hand side (RSeries) and left hand side (LSeries) of the bridge deck along traffic lanes are reported in Figure 11. In scenarios BS01and BS03, the explosives were placed close to the LSeries cables. Since the explosive is not close to the cable anchorage zone in scenario BS01-02, no cable detachment occurs. However, significant increase in the axial force in the cables close to the explosion was observed, and this can potentially lead to their rupture. In those cables close to the pylon, the axial loads increased up to 50 percent more than their capacity under a medium explosion. Under the large explosion, the axial force in the cables reached 2.5 times the axial load capacity of the cables. These results indicate the revision required to recommended DCR values in shorter cables in the case of an explosion on the deck, to produce no cable rupture under medium or large explosion.

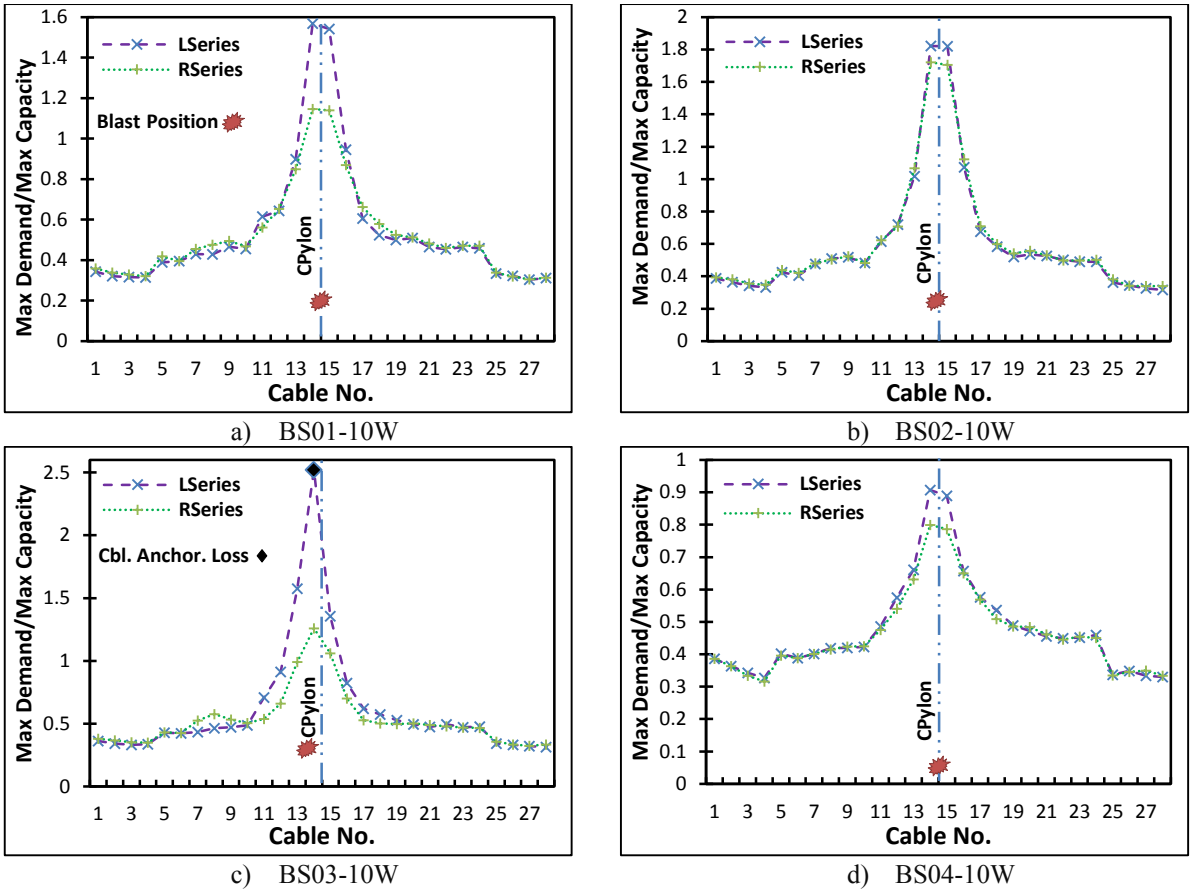

Figure 11 Maximum demand/capacity ratio for cables

DCR results in different blast scenarios

The calculated DCR values under a large explosion at different sections along the pylons are shown in Figure 12 and Figure 13 for different blast scenarios. It should be noted that the results are the maximum response at each section. DCR values and strain reached up to 1.12 and 0.02139 respectively in BS01 and the maximum stress at the explosion level increased to 460 MPa in a 10W explosion. Figure 12 indicates that all blast scenarios have less influence on the Further Pylon (FP). Moreover, because of the large change in cable forces at different BS cases, the upper part of the pylons in which the cable anchorages are placed experience larger blast effects and the DCR values at this location are up to twice the design DCR. In the case in which optimised designed sections are used along the height of a pylon and the design DCR are close to optimum value (say 90%) the change of the demand stress in the section can cause severe blast effects in that part and influence the instability of the pylon.

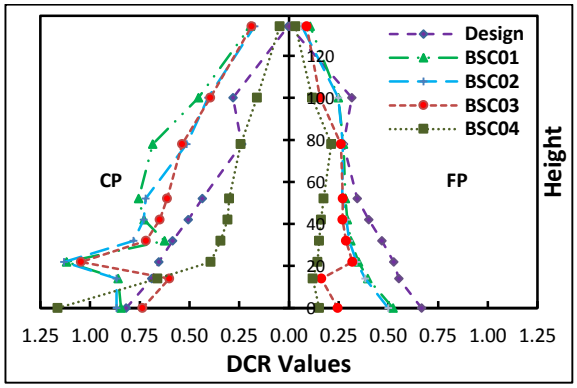

Figure 12 DCR values for CP and FP-10W

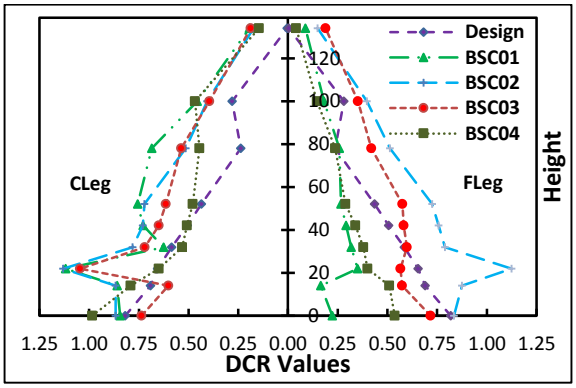

Figure 13 DCR values for CLeg and FLeg-10W

Optimising the pylon section

The variation of the pressure and impulse patterns on the surface of a structure between the maximum and minimum values is a function of the angle of incidence. This angle is formed by the line which defines the normal distance between the point of detonation and the structure, and the line which defines the path of shock propagation between the centre of the explosion and any other point in question on the structure surface (UFC-3-340-02 2008). The maximum reflected pressure and impulse occur when this angle is zero. Changing the angle to 35 degrees will decrease the reflected pressure up to 50% in a larger explosion. Consequently, a circular section with the same area of a rectangular section exposed to an explosion receives less reflected and impulse pressure. Since fabricating a circular section at a very large scale is almost impossible, a modified octagonal section is proposed and shown in Figure 14. This section has almost the same area as the existing rectangular section which means the weight of pylon is the same in both cases. The smaller second moment of area causes more vertical deflection in deck. If the same profile for the deck under self-weight is required, the axial forces in the cables should be adjusted. In this study, it is assumed that cables have the same axial load in new bridge so a new deck profile is achieved in the model.

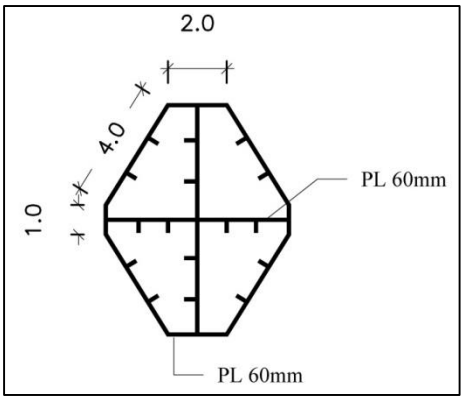

Figure 14 Proposed cross section

The maximum stress in the section at the blast level is the same as the existing section while smaller strain is observed in the section as indicated in Figure 15. The maximum stress and strain occur when the explosive is placed 6 m away from centre line of pylon (BS03). In this scenario, the standoff distance to the pylon is 7.5 m and the maximum angle of incidence is 16 degrees. Placing the explosive closer to the centre of pylon decreases the standoff but increases the angle of incidence, consequently reducing the maximum reflected and impulse pressure on the pylon. For smaller explosions (01-04W), no plastic deflection is observed in the pylon while the maximum DCR and strain value under a large explosion are 1.12 and 0.0088 respectively. Figure 16 shows the comparison of the maximum DCR values between existing rectangular section and proposed octagonal section with different explosive weight.

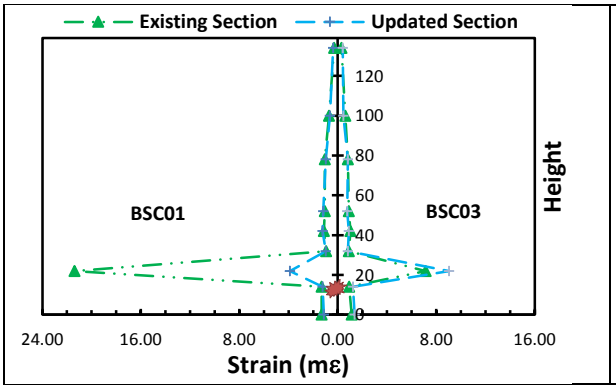

Figure 15 Effective plastic strain -10W

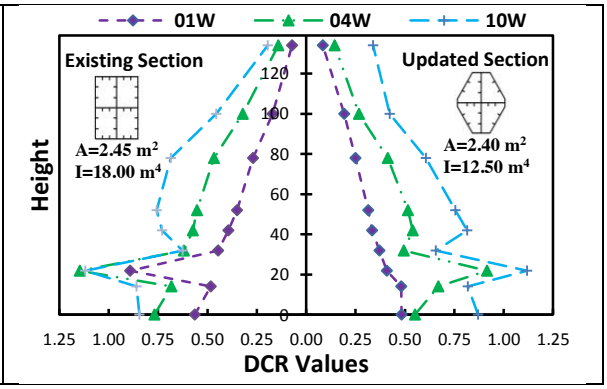

Figure 16 Maximum DCR values at each section

CONCLUSIONS

A detailed model of a hypothetical cable-stayed bridge was produced using LS-DYNA explicit finite element code and the dynamic response of the entire bridge and its components including the pylon, deck and cables were investigated under small to large explosions at different locations close to the pylon. With regard to the local and global responses of the bridge captured by the FE models, the following conclusions are drawn.

- The bridge remained almost intact under a small explosion with no repair required except for a small area in the deck right under the detonation point. However, deck and pylon close to the detonation point underwent plastic strains and rupture in medium and large size explosions. Although extensive damage and steel plate rupture along with large plastic deformations/strains in pylon were observed in some blast scenarios (particularly in large explosions, *i.e*. 10W), the damage did not result in global progressive failure of the pylon in any of the blast scenarios considered in this research. However, the structural components such as the deck and pylons in the vicinity of explosions required major repair and rehabilitation.

- In this study, cable rupture due to axial load exceeding the cable capacity was not considered, but the results of the FE model indicated that shorter cables in the vicinity of the pylon are more vulnerable to the rupture compared to other cables. The FE results also suggest that the revision required to the recommended DCR values in shorter cables in the case of an explosion on the deck to have no cable rupture under medium or large explosion.

- The proposed octagonal hollow section showed better performance under all blast scenarios with different explosive weights. The area of the pylon which is in the plastic region is significantly reduced because of less reflected pressure and impulse on the section due to its geometry. For small and medium explosions, little deflection was observed in the pylon while for a larger explosion a small area in the pylon experienced plastic strains. DCR values are in the same range in different sections whereas the maximum experienced strain is significantly different. Hence, no damage criteria can be stablished based on DCR values individually. The maximum strain in addition to DCR can effectively describe different vulnerabilities.

ABSTRACT

As a result of the increased risk of potential attacks worldwide, public concern about safety has been drastically elevated and designers were required to consider additional probable types of loading conditions such as impact and blast loads, especially when designing high profile structures. Building façade is the first element exposed to such loads and its response plays a vital role in the resulting amount of damage. Thin precast concrete panels are typically used in external building's façade for this purpose due to their favorable uniform shape and ease of construction. However, resistance of this system to impact load has been questionable. This paper presents the results of an experimental investigation conducted on two-way concrete panels. The presented study provides a deep insight to the behavior of two-way concrete panels, with different reinforcement configurations (including ferrocement) - under high intensity short duration load; namely impact loading. The test program included testing full scale reinforced concrete and ferrocement panels under impact load of a pendulum mass. The panels' performance under impact load is evaluated in terms of: the failure mode; the maximum impact loads sustained by the panels; the number of impact loads up to failure; and the maximum load transmitted to the supporting frame. The results clearly emphasize the significant influence of reinforcement on the overall resistance to impact loading. Different observations, discussed in this paper, provide an improved understanding of the behavior of reinforced concrete panels under impact loading, which would allow designers to make better and more informative decisions.

KEYWORDS

Building façade, two-way panels, ferrocement, experimental testing, impact loads.

INTRODUCTION

The effect of impact loading recently became of a significant importance to consider in structural design. Protecting civil and commercial structures from any threatening activities or sudden loading such as impact or blast load is not a luxury anymore. These types of buildings can experience impact load in many situations starting from a small strike, vehicle's collision reaching debris resulted from an explosion. Researches and designs for impact load were exclusively conducted for military applications and critical structures such as nuclear power plants. However, civil structures are exposed to potentially more danger than military applications, as usually most of the military applications are in better secured and in remote areas.

According to Murthy *et al*. (2010), the effect of impact load on concrete structures have been studied since mid-1700s, as there was a high need of designing high-performance missiles and protective barriers. Moreover, impact load effect was needed to be considered in designing concrete containment vessels for nuclear reactors, when it first started, to ensure absolute safety for the structure under any accidental load. In 1917, D.A. Abrams was one of the first researchers to conduct compressive tests on concrete with different strain rates. The research indicated that concrete strength was rate dependent (Haifeng and Jianguo, 2009). Old researches and studies, such as that conducted by Hughes and Beeby (1982) and Miyamoto et al (1991), concluded that application of equivalent static loads or similar static-based design methods would not be adequate for designing for impact loads. Also, Miyamoto et al. (1994), stated that it is hard to produce a single design method based only on the dynamic response of concrete structures under different impact loads. Impact loads can occur in many types and no single method will be able to predict the response of the structure under all these probable types of loads.

Impact load as defined by many researchers is a relatively large dynamic load applied to the structure in a relatively short period of time. As defined by Daudeville and Malecot (2011), impact loadings are mostly extreme loading cases with a very low probability of occurrence during the life time of the structure. Impact load can be in a form of abrasion or direct collision of solid masses with buildings reaching the debris flying

after explosions. The load-time history profile for impact load can best be simplified and described as a triangular load, where it starts with an initial large peak force at time zero and then decreases to reach zero in a very short period of time. Blast load is a large dynamic pressure applied to the structure in a very short period. Impact loading is similar to other short duration loads such as blast load. Blast events result in debris and fragments striking building components, thus causing impact.

Most of the building facades are made of precast concrete. Building façade is the first layer exposed to external loads, therefore it acts like the first line of defense against any external sudden load. The response of the facade dramatically affects the amount of damage and casualties. Ferrocement is a material that has been lately used in a wide range of applications in construction and prefabricated buildings. It can be used to form thin concrete panels used in shell roofs, water tanks, etc. According to Hartog (1984), in the early 1940s, slabs composed of cement mortars reinforced with superimposing layers of wire mesh and thin steel rods were first tested by Professor Pier Luigi Nervi in Italy. He found out that the slabs were flexible and they acted like a homogenous material and they were able to withstand severe impact loadings.

This research is studying the behavior of reinforced concrete and ferrocement two-way slab panels of the same dimensions and thicknesses for each material type under impact loading. The study examines the change in slabs response by changing the amount, spacing and location of reinforcement for the reinforced concrete panels and by using single versus double reinforcement meshes for the ferrocement panels.

EXPERIMENTAL PROGRAM

Test Specimens

This study will be testing four reinforced concrete and two ferrocement panels of dimensions 1480 mm x 1480 mm and thickness of 75 mm and 25 mm for R/C and F.C, respectively. Dimensions were chosen for ease of construction and movement. For the ferrocement panels, these dimensions are making the use of the reinforcing steel meshes more suitable and easier to handle. The purpose of the research is to study the effect of changing the amount and location of reinforcement keeping the impact loading and drop height constant. Table 1 summarizes the different types of all casted specimens. For R/C tests, specimen # 3 was chosen to be the control specimen, as its reinforcement (diameter 10 mm/ 15 cm) is the most repeated type of reinforcement in all specimens. Moreover, steel in R/C panels is most likely to be placed in the middle of the panel. The yield strength of the steel bars used in R/C panels is 360 MPa for diameter 10 mm (high tensile) and 250 MPa for diameter 8 mm (mild steel). For the ferrocement panels, the mesh used is a galvanized wire square mesh, to minimize rust and corrosion, of 1 mm diameter with 15 mm mesh opening and of yield strength 400 MPa. The compressive strength (fcu) of all R/C specimens tested is 43 MPa and 50 MPa for ferrocement specimens.

Table 1 Types of specimens

S #	Type	Reinforcement	Reinforcement Location	Testing Parameter
1	R/C	diameter 10 mm / 7.5cm	Middle	Rft. spacing
2	R/C	diameter 10 mm / 15cm	Middle	Control
3	R/C	diameter 10 mm / 15cm	Back	Rft. location
4	R/C	diameter 8 mm / 15cm	Middle	Rft.
5	F.C	2 Meshes	Front & Back	Rft.
6	F.C	1 Mesh	Middle	Rft.

Test Setup

The apparatus used for this study, shown in Figure 1, was designed for a previous research (Cherif, 2009) and it is available in the structural lab at the American University in Cairo (AUC). It is a pendulum type impact loading one, designed to hold specimens of different structural elements. A winch is used to raise the pendulum mass to the desired height and then release it to hit the specimen. A load cell is attached to the mass striking the reinforced concrete slab to measure the impact force. Different load cells are placed on the frame supporting the specimen to measure the reaction forces.

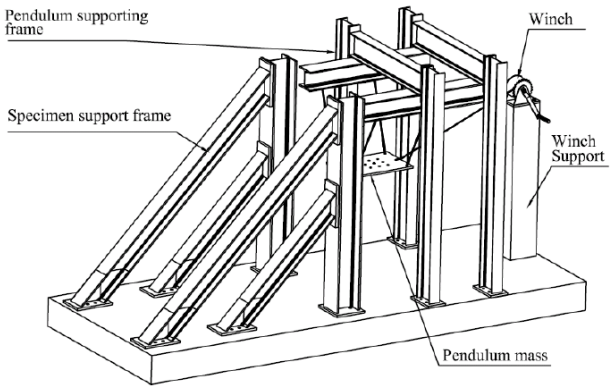

Figure 1 Schematic diagram of the impact apparatus (Cherif, 2009)

According to Cherif (2009), the apparatus is designed to support pendulum mass between 80 and 500 kg. "The total weight of the pendulum mass itself and the load cell is 68.52 kg (2.68 + 65.84 kg for the load cell and the pendulum mass respectively)" (Cherif, 2009). An additional weight in the form of sixteen steel plates was added to the pendulum mass, as shown in Figure 2. Each plate weighed 18 kg, resulting in a total impact mass of 357 kg, constant throughout the study. The impact force caused by the applied impact weight is recorded by the action load cell placed at the face of the impactor.

Figure 2 Impact mass

The drop height of the impact mass is constant during all tests and equals to 150 mm, measured from the datum, according to Bayoumy (2014). The impact action load cell was installed at the impact mass to record the value of the impact force hitting the slab at the center. Four load cells, placed approximately at the corners of the slabs, with equal distance in between, were used to measure the reaction forces transmitted to the slabs. For the surface of contact, a square steel plate of minimal thickness and dimensions chosen to have the same rectangularity of the slab is fastened facing the impact load cell to ensure smooth transfer of load to the slab and to avoid having the surface of contact variable. All the details about the experimental testing program is elaborated more in Bayoumy (2014).

Test Procedures

The experimental test procedures for the dynamic impact load test starts by preparing the specimens and installing all the instruments needed. The specimen is lifted by the lab winch to be placed and fastened in the apparatus. Then, the connection of all load cells and sensors to the compact recorder and the computer is checked. The mass is then lifted to a constant drop height of 150 mm measured from the datum (refer to Bayoumy, 2014) and then, left to free fall. Data recoding should be started concurrently with leaving the impact load to hit the panel and record for the first five seconds. The test is terminated when the specimen reaches the mechanism of failure or maximum ten hits, whichever happens first.

RESULTS AND DISCUSSIONS

This section of the paper will be presenting some of the output results obtained in the study conducted on the reinforced concrete and ferrocement panels, such as the peak action load and the support reaction loads.

Moreover, the crack pattern will be studied together with observing the number of hits needed by each specimen type to reach failure. A comparison between the results obtained for the two different materials will be presented.

Action Load

The recorded impact action load at the first hit only of each specimen will be presented, as it shows the full capacity of the specimen in carrying the load. For each hit, the impact mass rebounds to hit the specimen again with a much lower force due to the effect of damping. The first peak force is the one under consideration from which the period of the load (t_d) will be calculated.

Figure 3 shows the load-time history for the control specimen S# 2, which presents a typical load-time history and a good representative for other R/C specimens under impact load. For the ferrocement, the panels did not stand more than one hit and they failed, so the load cell read one peak force only at the time of the impact. The peak action load reached by S# 2 is 17.63 kN at time 1.02 sec. Figure 4 shows a typical shape for the first wave of the impact force for this specimen and a clear presentation of its period t_d, which is 97 ms.

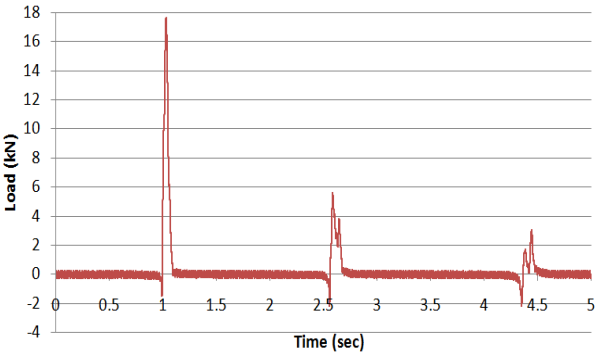

Figure 3 Load - time history (S# 2-1st hit)

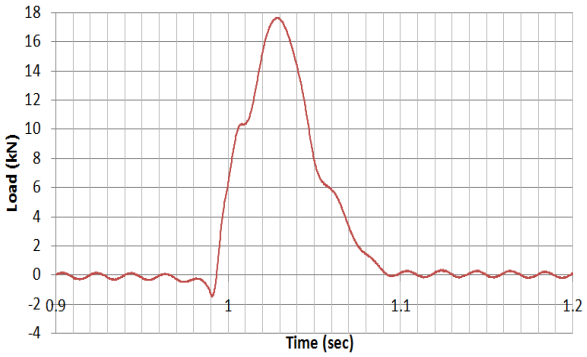

Figure 4 Period of load- td (S# 2-1st hit)

Table 2 shows the values of the peak action forces of the first hit for each specimen tested (R/C and ferrocement) and the time of occurrence. Also, it presents the period of the load for each panel. It can be noted from the table below that the lowest magnitude of action load and the highest period is recorded by S# 5 (diameter 8 mm / 15 cm - middle). It is expected that this specimen to be the weakest as it has the lowest reinforcement, so the specimen was not strong enough to resist higher load. The maximum value of the force was recorded by S# 4 (diameter 10 mm / 15 cm - bottom), where it reached a value of 28.7 kN. The action loads of the R/C specimens (S# 2A, S# 3A & S# 4A) are to some extent close, but much more than that of S# 5. The period of the action forces of the first hit for all R/C specimens ranged from 62 ms to 127ms. In general, it was noted that there is a relationship between the action load and the time period it takes; as the magnitude of the action load increases, the time it takes decrease. As for ferrocement specimens, S# 7A (one mesh) surprisingly recorded much higher value of action load than that for S# 6A (two meshes), but studying the action load alone is not enough to make a solid conclusion, we need to analyze the other results.

Table 2 Peak action loads and t_d at 1st hit

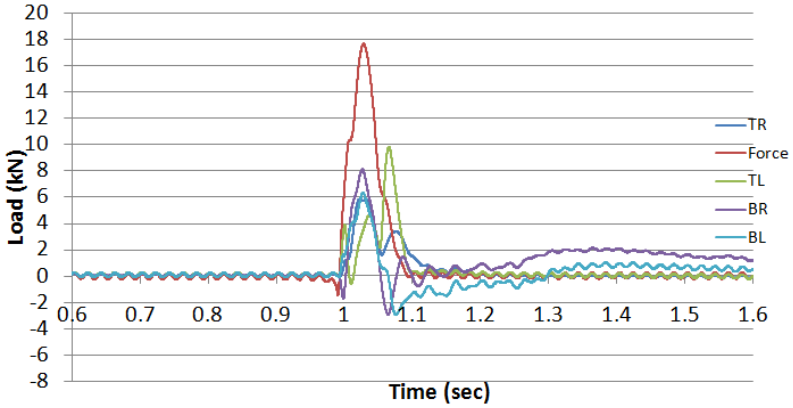
S #	Peak Action Load (kN)	Time (sec)	T_d (sec)
1	25.17	0.791	75
2	17.63	1.028	97
3	28.70	1.586	62
4	1.21	1.472	127
5	4.12	1.407	89
6	21.17	1.989	38

Reaction Loads

Reaction forces recorded at the supports are studied to anticipate the behavior of columns or the supporting system carrying the structure. Structure design shall be targeting a design of slabs and panels that can sustain the load and transmit it to the supporting system with minimal failure and risk on human lives. An analysis of the relationship between the action load, each support reaction, total reactions and the time delay between the action and reaction.

Action - support reactions

Figure 5 shows the relationship between the peak action force and all peak supports reactions for the control specimen at the first hit, where the load cell recorded the highest load values. By analyzing the results of this specimen, it was noted that at the first hit, there was much difference between the action force and each reaction force, but then, this difference started to decrease at later hits. At the first hit, the specimen shows large action force; much larger than the reactions. The action force in all hits is always higher than each support reaction force. Values of support reactions usually are close to each other except for two load cells at the first hit.



TR: Force in Top-Right Support
TL: Force in Top-Left Support
BR: Force in Bottom-Right Support
BL: Force in Bottom-Left Support

Figure 5 Action - reactions (S# 2 - initial hit)

Table 3 below presents the exact values of all specimens' action forces, reaction forces and the time delay between their occurrence for the initial, intermediate and final hits. All R/C specimens failed after tem hits with the exception of S# 4, the one with the lowest amount of reinforcement; it sustained only three hits. None of the ferrocement panels sustained more than a single hit. It can be noted from the table that the values of the supports reactions are not equal, cause of load cells sensitivity or specimen setting up, but they are generally close with some exceptions. Time delay in all specimens ranged from 0.8 ms to 39 ms. Some tests showed zero reaction time delay. When the specimen is rigid, load is transferred to the supports at the exact time of the impact without a delay in the reaction force. Some values of reaction delay are not significant as they are too small compared to the load duration. Reaction forces can be delayed cause of load cells accuracy as they may be not that sensitive to read the load at the exact time of impact. Also, the specimen may be not in touch with the load cell. Other reason for the time delay is related to the nature of the specimen itself; slab may be very flexible so that it takes time for the load to reach the support. Negative time delays are of small insignificant values and are considered measuring errors.

Table 3 Reactions & time delay

S #	Hits	Force (kN)	TR (kN)	T Delay (ms)	TL (kN)	T_{Delay} (ms)	BR (kN)	T_{Delay} (ms)	BL (kN)	T_{Delay} (ms)
1	Initial	25.17	11.8	2	18.9	36.4	9.67	6.2	10.0	7.4
	Intermediate	24.11	13.8	-1	14.9	39	9.81	5.4	10.2	5
	Final	21.29	10.3	0	16.0	33.2	9.23	0	9.53	0

Action - total reaction

The reaction forces of all four supports were combined together to evaluate the overall slab reaction force-time history. A summary of the values of the peak impact load reached and the peak total reactions recorded by the four load cells together with the ratio (Total Reaction / Action), that shows the percentage increase of reactions, are shown in Table 4 below. It can be shown that as the number of hits increase, the ratio of the total reaction forces to the action force increases. This can be explained as the slab is exposed to several impact loads, its stiffness decreases, so the magnitude of the action force resisted by the slab decreases and the reaction forces transferred to the supports increase causing an increase in the ratio between the total reaction and the action force. This denotes that S# 1 is a stiff specimen, while S# 4 is very weak. The exception can be found at S# 6 as the total reaction force was found to be less than the action force. This can be due to a loose contact between the steel plates placed in front of the load cells with the slab, so the force was dissipated as a result. Figure 6 illustrates the trend for the ratio with the number of hits for the reinforced concrete slabs at the initial, intermediate and the final hits. As for the ferrocement slabs, there is no trend to show as it sustained only one hit.

Table 4 Values of peak loads & total reactions

S#	Initial hit			Intermediate hit			Final hit		
	Peak Load (kN)	Peak Total Reaction (kN)	Ratio	Peak Load (kN)	Peak Total Reaction (kN)	Ratio	Peak Load (kN)	Peak Total Reaction (kN)	Ratio
1	25.17	42.08	1.67	24.11	45.16	1.87	21.29	38.76	1.82

Ratio: Total Reaction / Action

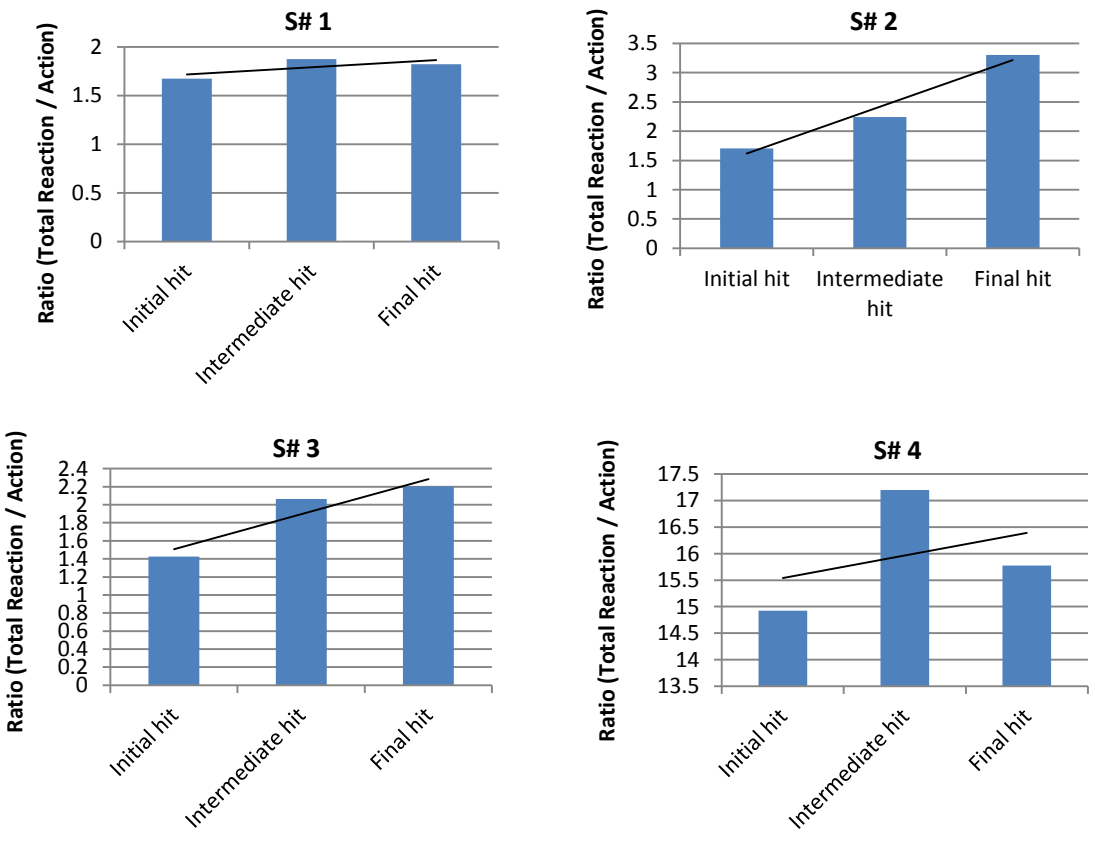

Figure 6 Ratio (total reaction/action) - hits

Slab damage

This section presents the observations of the slab damage for specimens throughout the test program. Full yield line development is the mechanism of failure - shape of failure - of the specimen. According to Mishra (2012), yield lines are typical crack patterns generated when ultimate moment is reached. They are straight and pass through the intersection of the axis of rotation of the adjacent slab elements and end at the supporting edges of the slab. The axis of rotation lies along lines of supports and passes over columns. Before cracking, the distribution of bending moments of reinforced concrete slabs progressively loaded to failure follows the linear static theory. After cracking, the distribution changes due to the decrease in flexural rigidity of the cracked portions. Yielding of reinforcing steel occurs with further loading causing bending moment redistribution.

Specimen #1:
The cracks on the back surface showed a fanned pattern coming out of the centre of the impact point and propagating, as shown in Figure 7. After the first hit, minimal hairline cracks were developed. The specimen was stiff enough to sustain the load and it did not fail after impacting ten hits. After the first hit, minimal hairline cracks were observed. There were no additional cracks during the successive hits. After the intermediate hit, few additional cracks of the same width appeared within the same fanned pattern. By the end of the test, there were no significant new cracks, but two cracks got widen around the centre of the impact region.

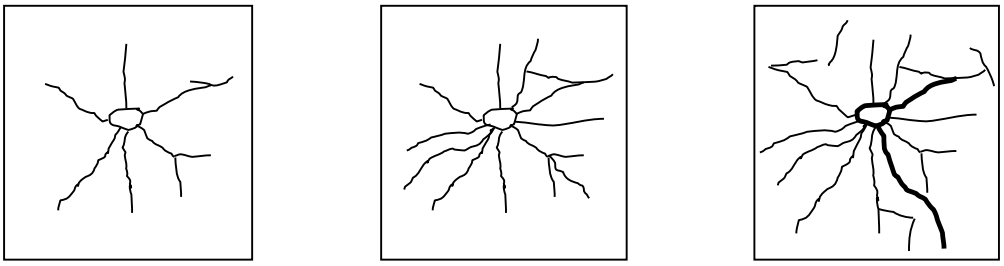

Figure 7 Cracks sketch- back side (S# 1)

Specimen #2:
Horizontal (transverse) cracks started to appear right after the first hit, as shown in Figure 8. By the fifth hit, few longitudinal cracks started from the center of the impact region and propagated along the longitudinal direction of the slab. At the seventh hit, there were no new cracks, but cracks became wider. Slab deflection remarkably increased after the seventh hit. By the end of the test, there were more transverse cracks. Cracks at the center of the slab at the impact region became wider and deeper.

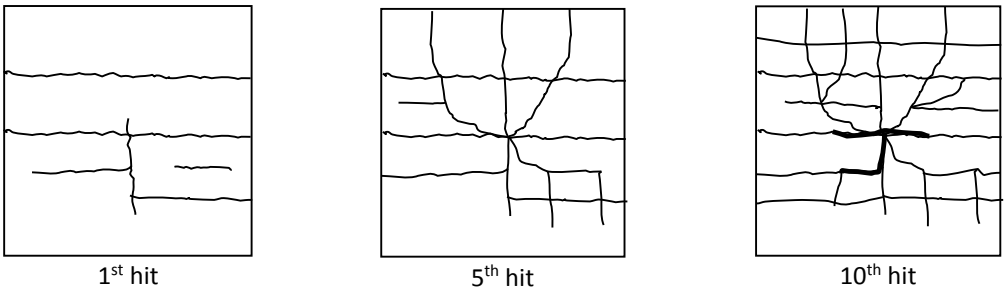

Figure 8 Cracks sketch- back side (S# 2)

Specimen #3:
Long and wide cracks appeared right after the first hit. By the fifth hit, few more cracks were developed and there was an increase in the crack width of cracks at the middle of the slab where the centre of the impact region. Most of the cracks at the back side of this specimen were vertical passing through the entire longitudinal direction of the slab. The cracking increased rapidly during the last five hits; the slab was affected most by the impacting load at the last five hits. As can be observed in the sketches in Figure 9, there is a rigid region located near the middle and the left side of the back surface. Cracks were developed above and below this area. This may be explained as during casting, the reinforcement at this specific region was shifted more towards the back of the slab thus, increasing the effective depth and the tensile reinforcement at this area.

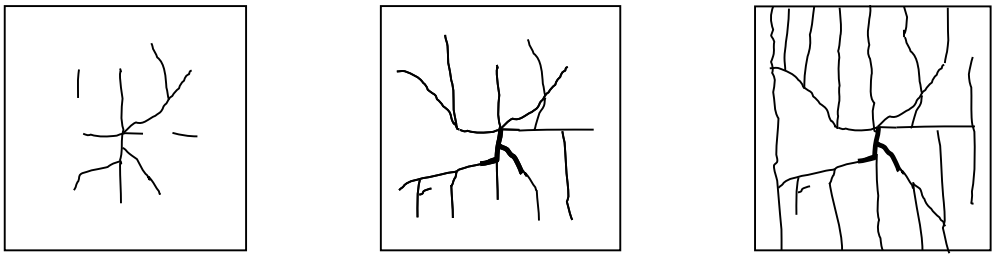

Figure 9 Cracks sketch- back side (S# 3)

Specimen #4:
Slab damage observation of this specimen is very distinctive from all other R/C specimens. This specimen is the weakest of all reinforced concrete specimens as concluded from studying the reaction forces. This conclusion is proved more by observing the slab damage. Recall that this specimen completely failed after the first three hits only and then the test was terminated. Starting from the first hit, the slab experienced cracks of very high thickness and depth. The overall number of cracks is minimal, but most of the cracks were wide and deep. Figure 10 shows cracks development throughout the three strikes at the region of the accelerometers installed at the middle and the quarter of the back side. The widest crack was found to be near the middle accelerometer, indicating that the centre of the slab was the weakest point. It is obvious that unlike the other specimens, this specimen experienced very wide and deep initial cracks and they got much wider and deeper with more impact.

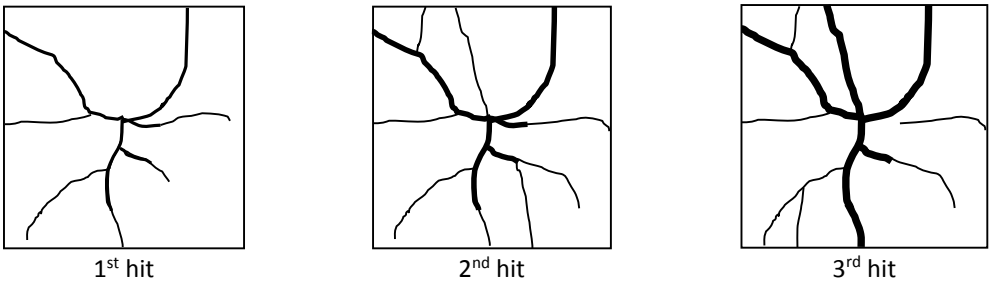

Figure 10 Cracks sketch- back side (S# 4)

Ferrocement:
Ferrocement specimens, shown in Figure 11, showed the weakest behaviour of all specimens tested. Both specimen did not withstand more than one strike and they completely failed. Slabs were fractured into totally separate parts after only one impact hit. For the one with double reinforcing mesh, the slab was split horizontally from the middle into two almost equal-sized parts. There were some cracks at the back side originated from the centre and propagating along the slab. The other specimen with only one reinforcing mesh was broken into several parts. It showed very weak resistance to the load and it is obvious from slab damage observation.

Figure 11 Ferrocement panels failure

CONCLUSIONS

An experimental study is introduced in this paper that tests the behavior of two-way concrete panels with two reinforcing materials namely; reinforcing steel and ferrocement, under impact loading. For the reinforced concrete panels, the reinforcement amount, spacing and location were changed. The results clearly show the significant influence of reinforcement on the overall structure resistance to impact loading. As the amount of reinforcement increases, the action load increases indicating a higher section capacity to resist more load and delay cracking and yielding of reinforcement. Moreover, the location of the reinforcement helps in enhancing the behavior. Panels of facades in risk of being subjected to impact loading are best designed with reinforcement placed at both sides as to account for all the possible directions of load as well as the rebound after impact.

The total reaction force is always higher than the action load. This ratio keeps increasing with the increase in the number of strikes, as the slab is getting weaker and its capacity to sustain the load is decreasing. This is due to the fact that it is a dynamic and not static problem, so inertia forces are also applied, which are function of the dynamic characteristics of the structure.

Slab cracking in a nature manner acts as a mean of load absorption. Therefore, façade panels subjected to impact should be designed in a way to sustain damage with enough ductility to break without shattering and thus avoids possible risks of causalities and injuries resulted from flying debris.

For the ferrocement, specimens with single and double reinforcing mesh were tested. Both showed very weak resistance to impact load relative to the reinforced concrete panels. The results emphasize that ferrocement panels can be used as sacrificial layers for building subjected to low impact loads.

Structural Health Monitoring

STRUCTURAL HEALTH MONITORING OF AN INNOVATIVE TIMBER BUILDING

ABSTRACT

A main focus in timber construction research is the development of innovative, sustainable and reliable structures. In order to determine the long-term structural behaviour of these novel structures, structural health monitoring is a valuable tool. In the past two years an innovative timber-hybrid pilot building has been conceived, designed and realized at ETH Zürich. The building contains four innovative structural systems, a post-tensioned timber frame, two timber-concrete hybrid floor systems using beech LVL, and a biaxial pure timber floor in beech wood. In order to fully understand the combined structural behaviour of these innovative systems an extensive monitoring system was set up. The dense sensor network was implemented along with the construction progress, in order to also quantify the effects of important construction stages on the structural behaviour (addition of significant loads, addition of stiffening elements, extreme changes in environmental climate, etc.). The installed setup includes 16 load cells, measuring the changes in the post-tension force in the frame, absolute deformation measurements, temperature and relative humidity sensors, as well as measurements of the moisture content of timber. The monitoring campaign is planned to be continued for several years beyond the completion of construction, in order to quantify the long-term behaviour during the use phase of the building.

KEYWORDS

Innovative hybrid-timber structure, Long-term structural performance, Structural monitoring under construction.

INTRODUCTION

Nowadays, the development of innovative structures, which are efficient and reliable throughout their life-cycle, is a main focus in the timber engineering field. Especially the implementation of hardwood elements opens up a whole range of new possibilities for timber structures. This is indeed favoured by the optimal strength and stiffness properties of hardwood. In addition hardwood is largely available in Swiss Forests and new implementations for the material are currently being investigated. Innovative structural systems are mostly developed and tested under laboratory conditions, i.e., small to mid-scale sample sizes in a controlled environment. From these tests valuable information about the short-term structural behaviour can be gained. However, the knowledge concerning the structural behaviour in an actual-scale building situation as well as in a long-term use, is limited. Therefore a pilot building demonstrating the implementation of hardwood as structural elements has been realized at ETH Zürich, under a project titled ``ETH House of Natural Resources (ETH HoNR)" (Leyder *et al*. 2015). The building allows for the quantification of the structural behaviour of several innovative structures in a real building situation. Starting from summer 2015, the building will be used as an office building by the Laboratory of Hydraulics, Hydrology and Glaciology (VAW) from ETH Zürich. The structure of the ETH HoNR is described in detail in Leyder *et al*. 2015. The following sections contains a short summary of the aspects that are most relevant for the monitoring setup.

The ETH HoNR comprises four innovative structural systems using especially hardwood. The main lateral and vertical load-carrying structure is a post-tensioned timber frame, using columns made of ash wood, hybrid timber beams composed of ash and spruce and a steel tendon. The tendons span over the whole building length at mid-height of the beam, in a horizontal hole in the middle of the beam cross-section. The post-tensioned frame was developed and extensively tested in the ETH laboratory (Wanninger and Frangi 2014, Leyder *et al*. 2014). Two types of laboratory tests were conducted, first a single column-beam joint specimen was tested and second a two-dimensional 19.5m long, three-bay (3*6.5m span) frame was tested. The exact same frame is implemented in the ETH HoNR building in a three-dimensional setup, with spans of 6.5m in both directions, leading to a floor section of 19.5m*19.5m. In Figure 1 the position of the frame is highlighted in the floor plan of the first timber story and in the section of the building. The columns are entirely produced in ash wood and have a cross-section of 380mm*380mm. The beams are hybrid timber beams with four lower lamellas in ash wood and the remaining upper lamellas in spruce wood. The total cross-section of the beams is 280mm*720mm. The semi-rigid joint between the columns and the beams is created via the post-tension force, no additional steel

elements are necessary. Therefore the construction of the frame is very fast (1) positioning of the columns, 2) mounting of the beams and 3) post-tensioning). The post-tension cables are post-tensioned to 700kN, which corresponds to a compressive stress of 3.5MPa in the beams. The small support attached to the column is mostly used for the mounting of the beams. Figure 3 a) shows a picture of the joint.

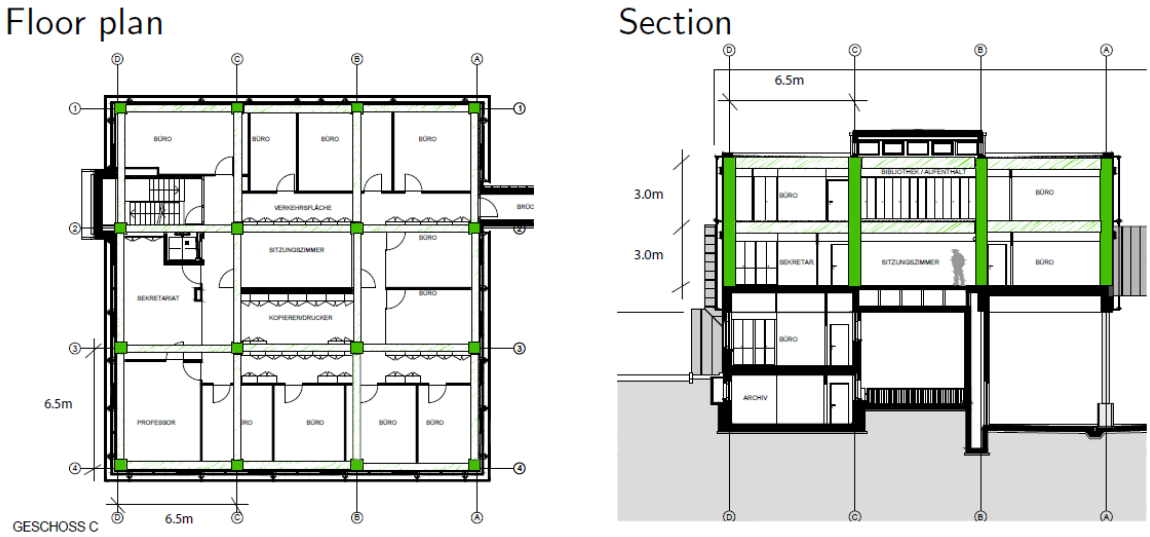

Figure 1 Floor plan and section of the ETH HONR building (Post-tensioned timber frame highlighted in green) (by mml architects)

The second innovative structural system is the mid-floor. It is a concrete-timber composite floor, composed of 40mm thick beech LVL plates and a 160mm concrete plate. The beech plates span also 6.5m and are supported on the frame. The concrete plate was cast on-site as a continuous element. This floor system was also developed at ETH Zürich, as described in Boccadoro and Frangi 2013. Figure 2 a) shows the installation of the beech LVL plates on the construction site of the ETH HoNR before the pouring of the concrete.
For the top floor (roof structure) two further innovative systems were implemented. One is a slab purely made of beech wood, with a bi-axial load-carrying capacity (Wanninger and Frangi 2012). This structure was only implemented in the centre field (elevated roof section in Figure 1), with an area of 6.5m*6.5m. The slab is composed of a 120mm thick 5-ply beech CLT plate (ply thicknesses: 20mm-30mm-20mm-30mm-20mm), rectangular posts in beech LVL (170mm high) and 40mm thick beech lamellas running cross-wise. The CLT plate was separated into three elements, which were then screwed together on site (transportable dimensions of 2.17m*6.5m). The addition of the lower cross-wise lamellas leads to a significant increase in stiffness and favours the bi-directional load distribution. Figure 2 b) shows a picture of the structure of the bi-axial floor from below (visible ceiling). The structure of the remaining 8 fields of the roof is a hollow timber-concrete composite floor. The lower plate of the hollow section is also a 40mm thick beech LVL plate, connected via posts (240mm high) to the top plate, a 70mm thick prefabricated concrete plate. The concrete plate is connected to the posts via diagonal screws, a system developed by the company Häring.

Figure 2 a) Beech plates for the timber-concrete composite floor b) Bi-axial timber floor in beech wood

The goal of the current research work is to study the structural behaviour of these different structural systems and their interaction, as well as the influence of environmental effects on the structural behaviour. Therefore several series of modal dynamic tests have been carried out during the construction phase and a dense monitoring setup has been implemented. The monitoring setup was implemented along with the construction progress in order to also capture the structure's reaction to the addition of loads, as well as to significant environmental changes (e.g. the change from outdoor climate to indoor climate). The building envelope is composed of a glass façade and a conventional roof (waterproofing – insulation – extensive vegetation). The indoor climate can be controlled by the user via the activation of shading elements and the opening / closing of windows. No automatic ventilation is installed.

Structural health monitoring is a very valuable tool for quantifying the structural behaviour and the condition of civil engineering structures. Especially for new and complex structural systems the implementation of a monitoring setup can help to verify design assumptions and to obtain information about the long-term behaviour of structures. With the development and construction of more and more complex structures, the necessity for monitoring is increasing not only in order to verify design assumptions but also to guarantee a long lifespan of structures (e.g. early detection of necessary repairs). In Aoki *et al*. 2003, many aspects of structural health monitoring are discussed and illustrated with implementation examples for infrastructural systems. The book by Glisic and Inaudi 2008 demonstrates especially the implementation of fibre optical sensors for structural health monitoring. An implementation of fibre optical sensors on a nineteen story building can be found in Glisic *et al*. 2003. In the ETH HoNR several high-end monitoring systems are implemented to analyse the structural behaviour, verify the design assumptions and to quantify the long-term behaviour of the timber structure.

The paper is organized as follows: The first part (monitoring - instrumentation) describes the implemented monitoring setup on the timber structure, followed by a section which presents and discusses monitoring results from the construction phase. Especially the results from the load cells measurements are then discussed in the discussion section and, the final section provides some concluding remarks along with further research efforts undertaken by the group.

MONITORING - INSTRUMENTATION

In order to fully quantify the structural behaviour of the building a dense network of different sensor types was implemented. The implemented sensors range from load cells, timber moisture content measurements to deformation measurements. In the following section the functionality and implemented setup of the sensor configurations will be illustrated.

Load cells

The post-tensioned timber frame is the main load carrying system for horizontal and vertical loads inside the building. The connection between the columns and the beams is assured only via the post-tension force, no additional steel connectors are added. Therefore the post-tension force in the tendons is a very important parameter for the entire stiffness and robustness of the building. Post-tensioning of timber is a novel technology, and the knowledge about the long-term behaviour (e.g. due to creep of timber) is limited. Indeed the post-tensioning creates large stresses perpendicular to the grain in the column area, which may lead to large creep deformations. Furthermore changes in timber moisture content may lead to shrinkage and swelling and therefore lead to additional stresses in the joint. This phenomena has been studied on small scale specimens documented in Wanninger *et al*. 2015. From these test results, a 30% loss of tendon force was predicted for the service life of a posttensioned timber structure. The post-tensioning of the building was designed according to these results. In addition a load cell was installed in each tendon, which constantly measures the post-tensioning force. Since the structure comprises 2 stories with 4 frames in each direction, in total 16 load cells were installed. Figure 3 b) shows a picture from the installation process of the load cell. The load cells is mounted between the tendon anchorage and the load distribution steel plate fixed to the timber column.

Figure 3 a) Joint between the column and the beams b) Installation of a load cell (tendon anchorage point)

Moisture content of timber

In order to better understand the relation between creep, shrinkage and post-tension losses, the moisture content inside the timber is monitored. The moisture content of the timber is measured via the electric resistance method, where insulated steel needles are drilled into the timber to a certain depth (measurement at the tip of the needle). A detailed overview of moisture content measurements in timber is given in Forsén and Tarvainen 2000, where also advantages and disadvantages of different measurement methods are discussed. In the building, several moisture content sensors (a pair of insulated steel needles) are implemented along the timber frame at a depth of 6cm (Figure 4 a)). On each floor 20 measurement points in beams and columns were installed. In the hybrid beams measurement points were installed in the ash wood and in the spruce wood. Furthermore the moisture content is also recorded in the beech CLT plate of the roof structure in the central field. In the 5-ply 120mm thick CLT plate the insulated steel needles were installed at 5 different depths (middle of each ply – depths of 10mm, 35mm, 60mm, 85mm, 110mm) (Figure 4 b)). As the 6.5m*6.5m CLT plate was assembled from 3 separate plates (2.17m*6.5m), 5*3 measurement points were installed.

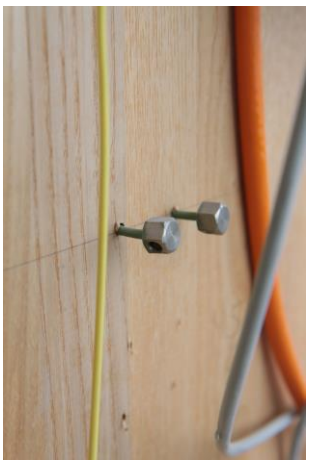

Figure 4 Moisture content measurement inside the timber a) Insulated steel needles inside a timber column b) Insulated steel needles inside the beech CLT plate at 5 different depths

Temperature and relative humidity

Temperature and relative humidity are also relevant parameters since they may significantly influence the moisture content of timber and therefore also its mechanical properties (Niemz 1993). During the construction period a single climate station was installed on the construction site monitoring temperature and relative humidity. It was assumed that throughout the construction site the climate is more or less constant, since the airflow is not hindered by any internal walls or the façade. After the installation of the walls and the façade, 12 combined sensors (temperature and relative humidity) were installed in 12 different rooms. Indeed, since the indoor climate can be controlled by the user himself (opening of windows / activation of shading), the climate might vary significantly from room to room.

Vibration sensors
In addition to the static monitoring setups, dynamic sensors were also installed inside the building. These were used during the dynamic test phases inside the building and will also be used during the use phase for structural identification and model updating on the basis of ambient vibrations. The idea is to evaluate changes in dynamical properties, and therefore system characteristics, and relate these to potential changes in stiffness, post-tension force, moisture content. The dynamic tests during the construction phase are documented in Leyder *et al*. 2015 and the ambient testing phase will start in summer 2015, after the building users have moved in.

Deformation measurements
Furthermore classical deformation measurements have been carried out. Two techniques were used, first classical levelling of mid-span points of floors and beams and second classical tachymeter measurements (also mid-span points of floor and beams). At the beginning an automated setup took hourly measurements of deflections. In a later phase, however, this was no longer possible due to the addition of the internal walls. Therefore only periodic tachymeter measurements were conducted combined with the classical levelling. The measurements were conducted in collaboration with the institute of geodesy and photogrammetry (IGP) of ETH Zürich.

The combination of these different monitoring systems is a complex task. Especially the analysis of the interaction between the different recorded parameters requires a detailed study and also quantification of external effects, that may not have been recorded (e.g. disturbances of the system due to construction works etc.). In the following section some results from the monitoring campaign will be presented. The focus lies on the results concerning the post-tensioned timber frame and moisture content measurements in timber.

MONITORING – RESULTS FROM MONITORING UNDER CONSTRUCTION

The construction of the building started in September 2013 and the sensors were installed along with the construction process. The first 8 load cells were installed with the first-storey timber frame in January 2014. The 8 load cells on the second story were added with the frame on the second story in July 2014. The moisture content measurements in the timber frame were installed at the same time as the respective frame. During the construction phase the air temperature and relative humidity were only recorded in a single position (climate station), as the construction was only protected by a weather proof membrane and the air could circulate freely through the whole structure. After the installation of the internal walls and the façade, several indoor climate sensors were distributed in different rooms and a climate station was installed on the roof in order to monitor also the outside climate conditions (February 2015). The deformation measurements of the first story started after the installation of the beech LVL plates on top of the post-tensioned timber frame (March 2014). The deformation measurements on the second story started after completion of the roof structure (November 2014). The starting dates of the measurements are also documented in Table 1. For the deformation measurements two different techniques were combined using each a different number of measuring points (~20), therefore no value is reported in the column “amount” in Table 1.
The presented data was recorded either with an automated data acquisition unit (load cells, temperature and relative humidity of the air) or manually (moisture content in timber). For the automated data acquisition daily mean values were calculated and are presented herein, for the manual measurement data was taken weekly (moisture content in the bi-axial floor) or every 3-4 weeks (deformation measurements, moisture content in the Post-tensioned (PT) frame). The data is presented until the end of May 2015. Monitoring under construction is a challenging task, as some construction works may require re-cabling of sensors and frequent power cuts may lead to losses of data. In this project data was recorded on as many days as possible, some gaps in the data could however not be avoided.

Table 1 Overview of instrumentation

	Amount	Start of operation
Load cells 1st story	8 cells	January 2014
Load cells 2nd story	8 cells	July 2014
Moisture content frame 1st story	21 locations	January 2014
Moisture content frame 2nd story	20 locations	July 2014
Moisture content bi-axial timber slab	15 locations	October 2014
Temperature and relative humidity (construction site)	1 location	January 2014 – January 2015
Temperature and relative humidity (closed building)	12 locations	February 2015
Temperature and relative humidity (outside on the roof)	1 location	April 2015
Deformation measurements 1st story	/	March 2014
Deformation measurements 2nd story	/	November 2014

Load cells

The following 2 figures (Fig 5 and 6) show the evaluation of the post-tension force in the 16 frames (LC1-LC8 on the 1st story, LC9-LC16 on the 2nd story), measured via the load cells. For the first story only values after March 2014 are reported, even though the frame was post-tensioned in January 2014. In March 2014 the frame was re-post-tensioned in order to calibrate the load cells. Therefore the data is presented starting from March 2014.

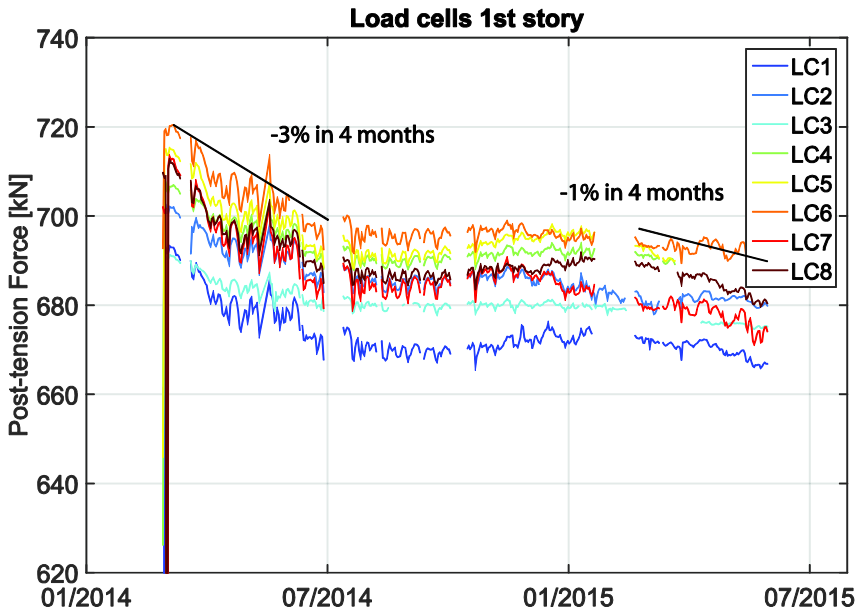

Figure 5 Post-tension forces on the 1st story (LC1-LC8)

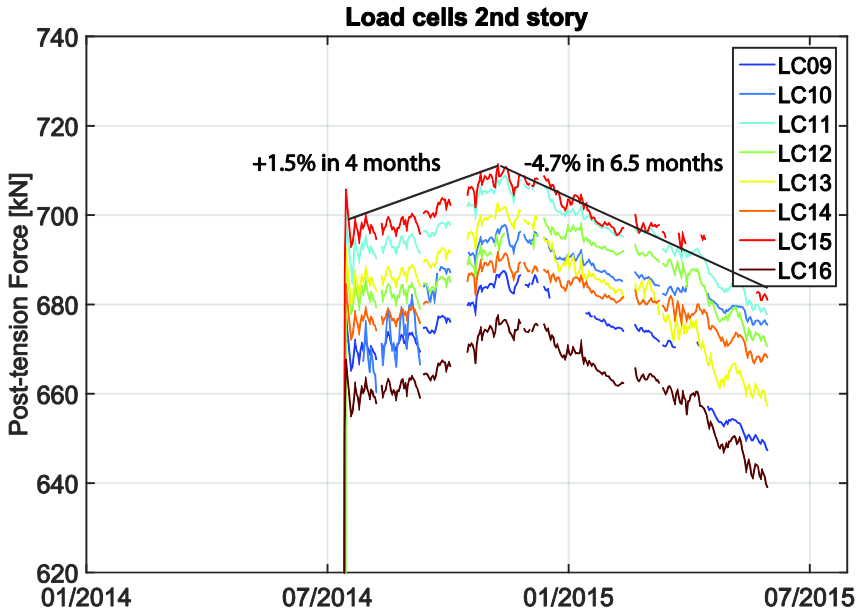

Figure 6 Post-tension forces on the 2nd story (LC9-LC12)

From the graphs it can be noted that all 8 load cells per story follow a similar pattern. The percentage of loss / gain in post-tensioning force is also indicated in the graphs. On the first story a 3% loss occurred during the first 4 months, followed by a stable phase of 6 months and then followed by another decrease of 1% in 4 months. On the second story the pattern is different, where first a 1.5% gain in post-tension force occurred during the first 4 months, followed then by a drop of 4.7% in the following 6.5 months.

Moisture content of timber

The moisture content of the timber was recorded periodically (approximately every 3-4 weeks). In figure 7 the measured values are shown for the 1st story frame (Fig 7a)) and for the 2nd story frame (Fig 7b)).

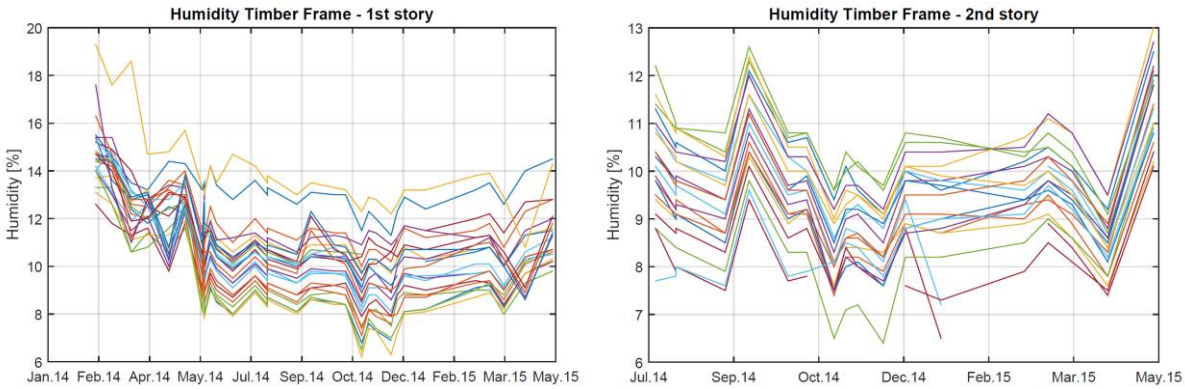

Figure 7 Moisture content in the post-tensioned timber frame at a depth of 6cm at different locations a) 1st story timber frame 2) 2nd story timber frame

For the 1st story frame the measurements in the timber frame show very high moisture content at the beginning of the construction. Indeed, due to several reasons the weather-proof membrane was not a 100% watertight and some parts of the frame were exposed to rain on a few occasions. Meanwhile the 1st story frame has dried out to a normal level (8 to 12% timber moisture content, except for 2 positions). On the 2nd story the moisture content inside the timber frame remained more or less constant over the entire measuring period (values between 8 and 12% moisture content). All measurement points show a similar trend and there is no trend difference between ash and spruce wood.

Furthermore, moisture content measurements were carried out in the beech CLT plate of the bi-axial timber slab. As mentioned before, the profile is recorded at 3 different locations, denoted A, B and C (Figure 8).

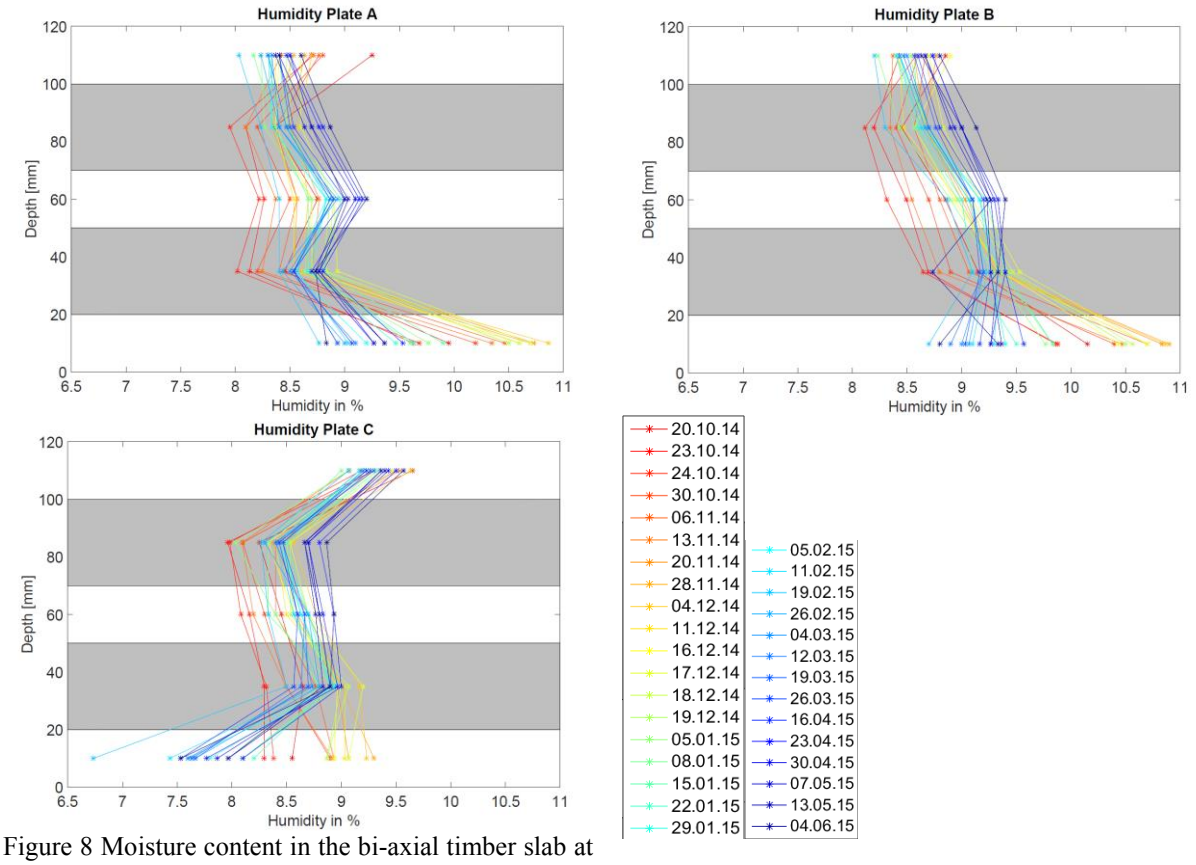

Figure 8 Moisture content in the bi-axial timber slab at 3 positions

The colour code indicates the evaluation of the moisture content from the installation of the floor (October 2014) (red) until the end of May 2015 (blue). Measurements were taken every week. The y-axis shows the depth of the measurement in the 5 ply CLT plate (cross layers are indicated in grey) and the x-axis shows the moisture content in timber. The moisture variation profile has slightly changed from the installation of the floor until the end of May 2015. In the lowest ply (room-side) the moisture content was reduced by ~1%, whereas the four upper plies show a slight increase in moisture content (~1%).

Temperature and relative humidity

In addition to the moisture content inside the timber also the temperature and the relative humidity on the construction site and later inside the building have been recorded. As mentioned before, the climate was first recorded at a single point (continuous line in Figure 9), and second recorded at 12 different locations (dashed lines in Figure 9).

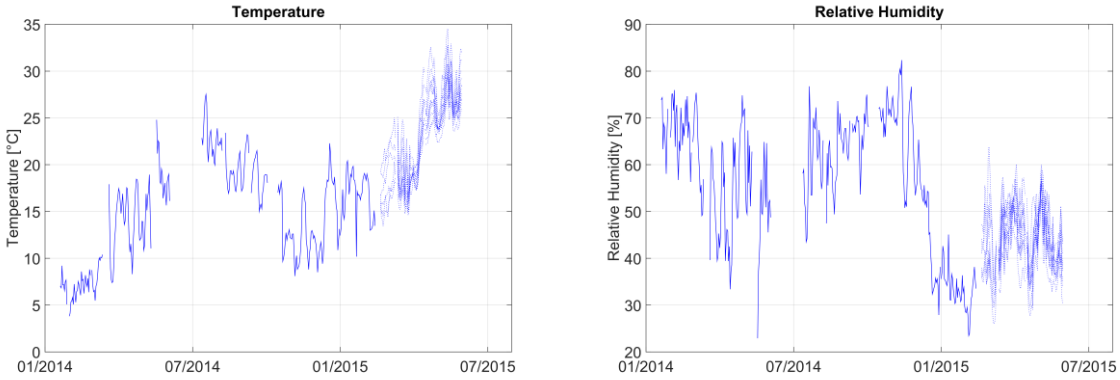

Figure 9 a) Temperature and b) Relative humidity (straight line until Feb 2015: climate during construction, dashed lines from Feb 2015 (climate after the building envelope was closed))

Before the completion of the building envelope in winter 2014/2015 the temperature and relative humidity measurements show a very high variability, as expected for outdoor climate. Temperatures increased during summer 2014 followed by a decrease towards winter. The heating inside the building was switched on in December 2014, the measurement system was however only switched to multiple locations in February 2015. The completion of the building envelope and the activation of the floor heating created a large drop in relative humidity (approximately from 60-70% to 30-50%). Since timber with small cross-section strongly reacts to large changes in relative humidity (Niemz 1993, Fragiacomo *et al*. 2011), several humidifiers were installed inside the building in order to avoid a further drop of relative humidity. The humidifiers shifted the relative humidity range from ~30-40% to ~40-50%.

DISCUSSION OF MEASURED POST-TENSION FORCES

The measured losses and gains in the post-tension forces can be compared to the small-scale experiments that were carried out in the laboratory (Wanninger *et al*. 2015). Therein, two series of specimens were monitored, 1 series in a controlled environment and 1 in an uncontrolled environment. During the first 3 months a loss of 6% in post-tension force was recorded in the controlled environment and a loss of 12% in the uncontrolled environment (Fig. 16 in Wanninger *et al*. 2015). The specimens used in these tests had a cross-section of 240mm*120mm and were post-tensioned to 3MPa. On the construction site of the House of Natural Resources building, however, the cables were post-tensioned to 3.5MPa and the cross-section of the beams is 720mm*280mm. For both setups, small-scale laboratory tests and building measurements, the moisture content was recorded at a depth of 60mm. One main difference is however the location of the tendon, which runs at a depth of 60mm for the small scale specimens and at a depth of 140mm for the frame of the building (measured from the side of the beam). These differences in cross-section size might explain the much smaller losses in post-tension force observed inside the building. Indeed, the paper by Friagiacomo (Fragiacomo *et al*. 2011) shows that the correlation between changes in relative humidity and the moisture content of timber (mean value) is strongly dependent on the cross-section size (Fragiacomo *et al*. 2011). This can explain why the change in relative humidity has a much stronger effect on shrinkage and swelling for the small scale specimens and therefore leads to higher losses in post-tension force for the small-scale specimens.

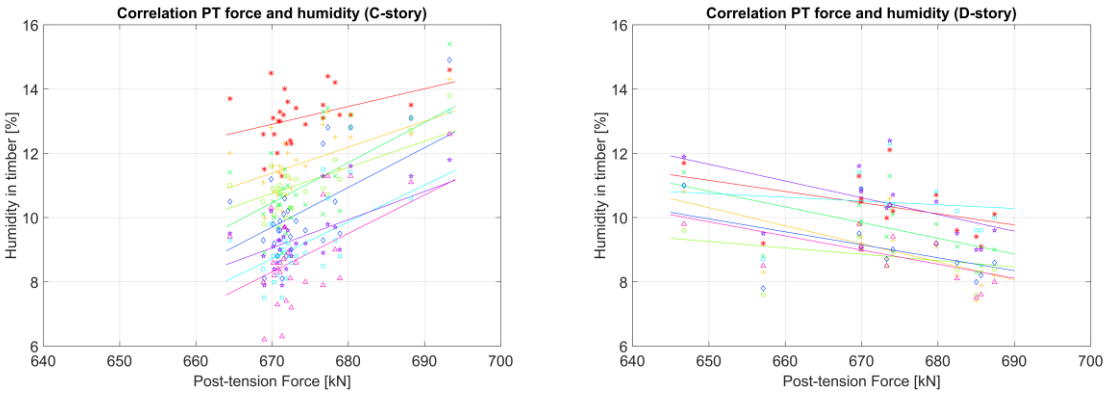

Figure 10 Example of the correlation between the post-tension force in a frame from the 1st story (left-hand figure) and 2nd story (right-hand figure) and the moisture content measurement at 8 locations along the frame (each location is denoted with a different symbol and colour). The linear regression lines were added in the same colour.

Indeed, the correlation coefficients between the relative humidity measurements and the losses / gains in post-tension force were calculated and were found to be very low for the building frame. In addition however also the correlation coefficients between the load cell measurements and the moisture content inside the timber cross-section were calculated. As an example, Figure 10 illustrates the correlation for one load cell and moisture measurements along the corresponding frame (at 6cm depth). For the 1st story frame a mean correlation coefficient of 0.74 with a standard deviation of 0.1 could be found. For the 2nd story the mean correlation coefficient is -0.55 with a standard deviation of 0.2. This indicates that for the 1st story there is a clear correlation between the initial drop in post-tension force and the initial drying of the timber (shrinkage). During the summer period of 2014 the drying of the timber cross-section stopped (high outdoor relative humidity), which is manifested by a stable phase in the post-tension force. The final decrease phase (Feb – May 2015) cannot be clearly correlated to the moisture content. For the 2nd story, the correlation is clearly less significant. Indeed the timber moisture content is nearly constant, whereas however the load cells indicate an increase and decrease in post-tension force. The moisture content measurements were only carried out every 3-4 weeks, this period may have been too long to clearly indicate a significant trend. The measurement frequency will therefore be increased to bi-weekly measurements in the future. Furthermore there might be a strong moisture gradient over the cross-section which also influences the post-tension force and cannot be measured by the current setup. A hypothesis is, that the timber members of the 2nd story were well dried (moisture content of ~10%) when they arrived at the construction site, so that the moisture content would first increase (high relative humidity) and then decrease with the start of winter and the heating period. This would then linearly correlate with the post-tension force (increase in moisture content leading to an increase in post-tension force and decrease in moisture content leading to a decrease in post-tension force). Indeed an increase in moisture content would lead to swelling of especially the column section and therefore induce higher stresses in the column-beam joint. Unfortunately, this trend could not be captured by the moisture content measurements. Other factors like creep, in combination with the addition / removal of loads may also have influenced the post-tension force. These factors will be further investigated in the future.
The difference of the post-tension force losses between the 1st and the 2nd story may mostly be explained by the different climatic conditions and also the initial moisture content of the timber members. The frame of the 1st story was mounted in winter time and had a rather high initial moisture content. The timber members dried out to an equilibrium condition in summer 2014. This seems to be a valid explanation for the larger initial drop in post-tension force. The frame on the 2nd story was mounted in summer 2014 and the timber members had a lower initial moisture content. These 2 factors can explain why the loss in post-tension force between the 1st and the 2nd story strongly differ. It is expected that the behaviour will become more similar in the use phase of the building, were the climatic conditions will exhibit lower variations.

CONCLUSIONS

An innovative hybrid timber building is subjected to an extensive monitoring campaign. The paper presents first results from the measurements during the construction phase. Especially the losses in post-tension force are commented and put into relation with the indoor climate variations and the moisture content measurements inside the timber cross-section. The following conclusions can be summarized:

- The loss in post-tension force on the 1st story correlates strongly with the changes in moisture content in timber.
- The loss in post-tension force on the 1st and 2nd story has no correlation with the changes in relative humidity. This may be explained by the large dimensions of the beam and column cross-sections.
- The loss and gain in post-tension force on the 2nd story cannot be explained via a direct correlation with the moisture content measurements. Other factors may be responsible for these changes.
- The difference in the loss of post-tension force between the 1st and the 2nd story may be explained by the different climatic conditions at the time of erection and also by the difference in initial moisture content.
- The moisture content in the bi-axial timber slab remained nearly constant. A drying out of the lower plate of ~1% was observed, which can be linked to the large drop in relative humidity after the closing of the building envelope.

At this point, the monitoring during the construction phase of the building was presented. The installed monitoring setups will however remain in operation for at least 3 more years after the beginning of the use phase of the building in summer 2015. From these measurements further insights regarding the long-term behaviour of the structure under operation will be gained, via monitoring of the evolution of structural properties with respect to influencing agents such as temperature, humidity and post-tension losses.

ABSTRACT

To realize in-situ structural health monitoring of critical infrastructure such as bridges, we present a powerful, but also low power and flexible, wireless sensor node utilizing a wake-up transceiver. The sensor node is equipped with several kinds of sensors, such as temperature, pressure and acceleration for in-situ monitoring of critical infrastructure. In addition to these commonly used sensors in wireless sensor networks, some nodes are equipped with global navigation satellite system receivers (GNSS) and others with tilt and acceleration sensors of very high accuracy that were developed by Nothrop Grumman LITEF GmbH. We present a low power wake-up multi-hop routing protocol that is able to transmit data with little overhead by supporting the use of wake-up receivers in combination with long-range communication radios. The wireless sensor nodes and the routing protocol are tested at a large-scale highway bridge in south-west Germany, where a prototype network was installed in June 2015 following a first test installation earlier in June at the same bridge. A gateway node equipped with a Global System for Mobile Communications (GSM) modem transfers the network data to a remote server located at the University of Freiburg.

Monitoring of critical infrastructure, Wireless Sensor Network, Wake-up transceiver, wake-up multi-hop routing protocol, GNSS receiver

INTRODUCTION

Structural Health Monitoring (SHM) of critical infrastructure such as bridges can provide important information about structural performance and may help to detect anomalies or threats originating from damages or deteriorations at early stages. SHM can also be used to estimate remaining life time, to assist in bridge maintenance planning, to verify construction designs and to deliver important data in case of disasters or extreme events (Chang et al. 2003, Ko et al. 2005). According to Ahlborn et al. 2010, there exist three different techniques of SHM for bridges that can be classified into in-situ, on-site and remote monitoring techniques. In-situ monitoring techniques use sensors such as temperature, humidity, strain gauges, acceleration and others installed directly at a structure, whereas on-site monitoring techniques use more complex sensors such as laser scanner, different RADAR techniques and others that are brought to a structure during the event of monitoring. Remote monitoring is done from a greater distance, for example by analysing photographs of the structure taken from satellites or airplanes.

In respect to SHM, one important measurement is the three dimensional displacement of a structure or of parts of it. These measurements can be done by using on-site sensors such as laser scanners (Ahlborn et al. 2010, Yi et al. 2013, Cross et al. 2013) or by using in-situ measurement results provided by Global Communication System (GPS) receivers (Knecht and Manetti (2001), Yi et al. (2012), Meng et al. (2007), Nickitopoulou et al. (2006), Psimoulis et al. (2008)). In contrast to optical sensor systems, for example laser scanners or total stations, a GNSS based monitoring system provides several advantages, such as weather independency, absolute displacement measurements, autonomous operation and no need for line-of-sight connection between different measurement points (e.g. Yi et al. 2013). Applying Near Real Time static baseline processing, displacements of the range of 5 mm or greater can be detected as well as oscillation frequencies of up to and above 4 Hz (Günther et al. 2008. Psimoulis et al. 2007, Yi et al. 2013). Meng et al. (2005) recorded the dynamical response of the

Wilford Bridge in Nottingham, using Global Positioning System (GPS) receivers in combination with accelerometers to validate the data and improve the monitoring system performance.
Especially in-situ monitoring systems are often realized with the help of Wireless Sensor Networks (WSNs), as they are cheap and easy to install on existing structures (Chang et al. 2003, Ko et al. 2005, Ahlborn et al. 2010). WSNs consist of sensor nodes which are self- or battery-powered small units and communicate wirelessly to each other.

For long-term monitoring, sensor nodes are unattended over longer periods of time, since they are placed in remote areas where replacing of batteries is not feasible. Therefore, long node lifetimes are desired and the power consumption of WSNs has to be minimized. A possible way to save energy is an energy efficient communication protocol such as the on-demand communication approach (Al Ameen at al. 2010). Here, wireless sensor nodes have no synchronized listening and sleeping phases, but listen permanently in a low energy stand-by state and wake up to full functionality only after receiving a wake-up call or triggered by a sensor. An advantage of the on-demand communication approach is the low latency: since there exist no scheduled sleeping phases, messages can be sent immediately. For example, if a sensor detected a critical signal, this message may be transmitted to the gateway without further delay as would be the case when long and uninterruptable sleeping phases are implemented.

Wardhana et al. 2003 analyses the reasons of bridge failures in the United States between the years 1989 and 2000. They analyse more than 500 failures of bridges, which had an average age of 52.5 years. Their analysis shows that the failures mostly took place during service life time and that 83% of the failures were triggered by an external event, like floods, earthquakes, fires, hurricanes, overloads and impacts of vehicles. This means, that continuous monitoring of bridges can be used to early detect such events or at least their impact which could be critical to the infrastructure. Taking this into account, on demand communication protocols can potentially save precious time by quickly broadcasting sensor data of triggering events. At the same time, on demand communication protocols can save energy by performing low duty cycling and asynchronous measurements.

Another advantage of wake-up transceivers, which support on demand communication, is their enhanced robustness because no clocks need to be synchronized. So, the embedded software may be reset at any time, e.g. if a fatal error state occurs. New nodes can easily be integrated into an existing network which is running in low duty cycle periods. Additionally, pulling data from the network or demanding extra measurements can be done easily – a great advantage during bridge maintenances. But the on-demand communication approach also poses new challenges, as sending of a wake-up signal can be more expensive than sending of a communication message (Bannoura at al. 2015). Another challenge arises from the lower sensitivity of the wake-up receiver compared to the sensitivity of the communication radio, which requires several wake-up messages to reach a sensor node in communication range (Bannoura et al. 2015). Therefore, protocols have to be used that are able to cope with these challenges.

Here, we present a powerful but flexible wireless sensor node utilizing the wake-up transceiver. The node is equipped with different kinds of common and cheap sensors, such as temperature, pressure and acceleration. Additionally, there exist sensor nodes that are equipped with a very accurate tilt sensor developed by Nothrop Grumman LITEF GmbH and sensor nodes that are equipped with high performance GNSS receivers from NOVATEL to improve the performance of the structural health monitoring system. We present a WSN installed on a large-scale highway bridge in south-west Germany and introduce a static wake-up multi-hop routing protocol. A Global System for Mobile Communications (GSM) gateway node is used to transfer the network data to a remote server.

RELATED WORK

Several WSNs have been introduced for SHM of bridges which usually consist of sensor nodes that acquire process and transmit data. Lynch and Loh (2006) give a comprehensive overview of wireless sensor node prototypes for SHM in academic and commercial context available during the years 1998 – 2005. In their work Lynch and Loh emphasize on the lower cost of installing a wireless monitoring system compared to tethered systems. They also reviewed available operational systems (OS), radio transceivers and data processing techniques to be used for SHM systems. Lynch et al. (2006) present a WSN consisting of 14 nodes to measure the acceleration response of the Geumdang Bridge.

Kim et al. (2007) present in a WSN deployed on the Golden Gate Bridge consisting of 64 nodes that measured ambient vibrations, and a base station that was a Laptop. Due to the large size of the Golden Gate Bridge the network included a 46 hops multi-hop route. Similar to this work, Whelan et al. (2009), Bocca et al. (2011) and

Sim et al. (2014) present a WSN consisting of several nodes that were connected by a single-hop star-type network to a base station (microcontroller notebook).
Kurata et al. (2011) presented a WSN on the New Carquinez Suspension Bridge in California based on the Narada wireless sensing units which feature a 2.4 GHz IEEE 802.15.4 radio standard. The Narada node, equipped with 5-AA batteries, had a lifetime of 40-45 hrs which could be extended by 60 % by using sleep modes. The sensor nodes send their data to a Narada server base station using single-hop links. The more powerful base station consisted of a low-power computer running a Linux OS and was equipped with a third generation (3G) modem to deliver the data to a remote database server.

Chae et al. (2012) successfully monitor the Yonjong Bridge with a WSN consisting of 45 nodes and a gateway station. The gateway includes a commercially available communication module to upload data to a remote server. The monitoring test provides three months of continuous data with 90 % transmission rate. Communication was based on commercial ZigBee modules but the authors did not provide figures on energy consumption of the modules. The installation includes dynamic (accelerometer and strain gauge) and static (wind and temperature) sensors which were connected as star- or mesh type network, respectively. The data are sent per single-hop to the gateway. To cover longer distances between node and gateway, directional antennas are used.

Hu et al. (2013) designs a WSN to monitor the Zhengdian Highway Bridge based on nodes, which uses a MSP430 microcontroller and a CC2420 radio. The nodes are running TinyOS, which uses MintRout to send data over multi-hops to a base station. Including an energy storage of 6750 mAh, a node is able to monitor continuously for around 168 hours, or when choosing a sampling period of 1 hour/day, lifetime can be extended to 168 days. The base station is connected via a USB connector to a powerful host computer.

In contrast to the studies above, we present a SHM system based on ultra-low-power wake-up sensor nodes, which supports the use of flexible and asynchronous measurement cycles ranging from seconds to hours and days. In sleep mode they consume only around 9 µW energy and due to their flexibility, their lifetime can be enhanced without losing precious time in case of important events, compared to fixed duty cycling measurements. The base station, equipped with a GSM modem, submits data to a remote server. A wake-up multi-hop network protocol is presented, which supports the use of the introduced sensor nodes

WIRELESS SENSOR NODES

The wireless nodes used in this work are based on the sensor node introduced by Gamm et al. (2012). Featuring a wake-up transceiver, the nodes combine the advantages of fast communication, a small antenna and low current consumption. The microcontroller utilized on the boards is a powerful 32 bit EFM32 Gecko manufactured by SiliconLabs. It has many build-in features and interfaces like SPI, I^2C, multipurpose GPIOs and a 12 Bit ADC just to name some of them. It provides up to 128 kB RAM and several low power states to reduce energy consumption. To realize long-range communication a CC1101 radio is used that has a current consumption of 30 mA when transmitting at 10 dBm output power at 868 MHz. Its sensitivity is around -104 dBm. The 125 kHz wake-up receiver (AS3932) from austriamicrosystems has a current consumption of only around 3 µA in listening mode and, in combination with the passive modulation path, the board has a wake-up sensitivity around -50 dBm (Gamm et al. 2012).

The sensor nodes are equipped with a high precision realtime clock (PCF2129T) that has an accuracy of +/- 3 ppm. To store data from sensors and from the network each board has a MicroSD card that provides several GB of storage. To minimize power consumption, a circuit was developed that can be used to switch the SD-Card completely OFF by the microcontroller. The node is equipped with a temperature sensor (DS18B20), a three axis acceleration sensor (LIS3DSH) and a precision altimeter/pressure sensor (MPL3115A2). In wake-up listening mode the node has a current consumption of around 9 µW.

Figure 1 (a) shows a schematic of a GNSS (Global Navigation Satellite System) receiver node including the passive wake-up path. The antenna is connected by a switch either to the main radio or to the wake-up receiver. The wake-up signal is obtained from the 868 MHz signal via the passive AM-Detector that consists of the matching network, a rectifier and a low pass filter. In case the wake-up receiver detects a valid input signal it triggers an interrupt in the microcontroller that toggles the antenna switch to the main radio. In this state, the sensor node is ready to receive and transmit communication messages. Relay nodes are similar to sensor nodes except they have no sensors on board. The base station is additionally equipped with a Global System for Mobile Communications (GSM) modem to transfer data to a remote server. To save energy, the GSM modem can be switched OFF by the microcontroller when the modem is not needed.

GNSS Sensor Node

Figure 1 (b) shows a photo of the GNSS (Global Navigation Satellite System) receiver node. It is based on the same hardware as the sensor nodes introduced above. A NOVATEL OEM615 GNSS receiver module can be connected to the board by using a simple 20 pin connector. A UART interface is used to configure the GNSS module and to read out the GNSS messages periodically. Figure 1 (a) schematically shows the GNSS receiver node including its hardware blocks. The NOVATEL OEM615 module supports GPS, GLONASS, Galileo and Compass frequencies, measurements up to 20 Hz and real-time kinematic positioning. Since the GNSS board draws around 6 A during start-up, a power supply circuit on the sensor node delivers this high peak currents for a short time. In active mode, the GNSS receiver draws constantly around 500 mA. To reduce the power consumption of the GNSS receiver node, the GNSS module is activated only periodically and can be switched OFF completely during times when it is inactive. Depending on the amount of satellites in view of the antenna, the amount of received data varies between several Bytes to several Kbytes per message. To send this amount of data wirelessly to the base station a wake-up multi-hop routing protocol was developed that is capable of sending data with little overhead. The protocol is introduced in the next section.

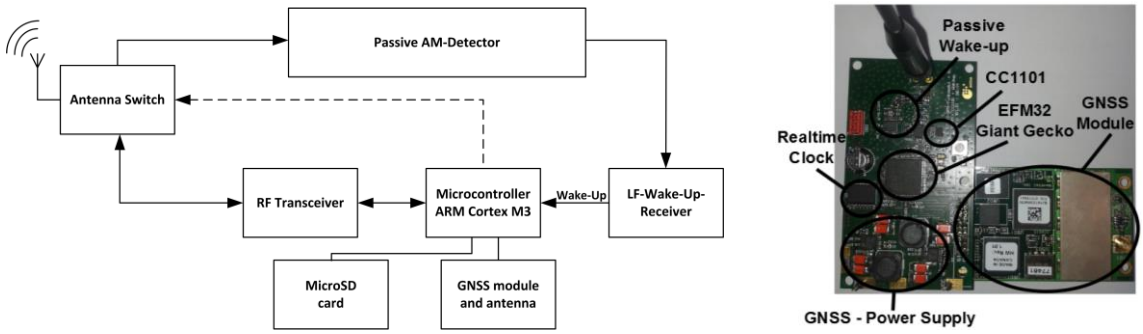

Figure 1: Photo of a GNSS receiver node (a) and its schematic including the passive wake-up path (b)

Tiltmeter and Acceleration Sensor Node

Figure 2 schematically shows the tilt and acceleration sensor node. The sensor node is equipped with a very accurate tilt and acceleration sensor developed by Nothrop Grumman LITEF GmbH. The sensor has a reproducibility of more than 50 µg (one sigma) over the tested temperature range. The sensor is connected to the sensor board via the SPI interface and indicates a completed measurement by a busy signal. Internally the sensor uses a microcontroller, a digital to analog converter, an analog to digital converter and the sensor itself (MEMS-Chip). The board has a current consumption of around 80 mA when active and can be switched OFF completely to safe energy.

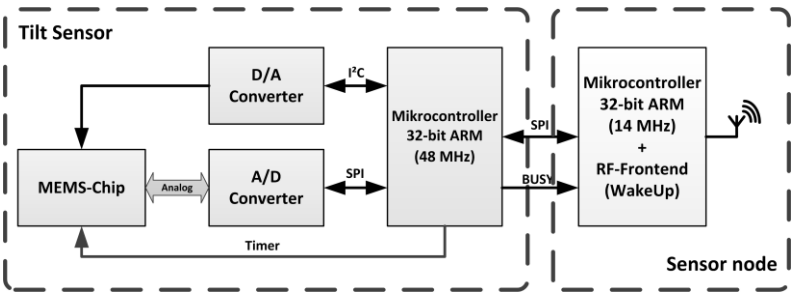

Figure 2: Schematic of the newly developed tilt and acceleration sensor connected to the wireless sensor board via SPI

WAKE-UP MULTI-HOP ROUTING PROTOCOL

Since to our knowledge no communications protocols for WSNs have been published, which support the use of wake-up transceivers, a new communication protocol needs to be developed. It should support both: wake-up receivers and long-range communication radios. Since the range of the wake-up receivers is small compared to that of the main radio, data and wake-up transmission is realized by a multi-hop routing protocol that supports sending of wake-up messages and data. The protocol stack consists of several layers. The lowest layer is responsible for the waking up of neighbouring nodes. The second layer handles single-hop message

transmissions and the top layer routs messages and forwards wake-up signals along multiple hops, if the destination is not a direct neighbour.

As mentioned above, the sensitivity of the wake-up receiver is lower than that of the communication radio and data can be sent over longer distances than wake-up messages. The routing protocol as depicted in Figure 3 makes use of this behaviour: by building a chain of woken nodes and transferring data to the most suitable receiver, nodes in between can be skipped during data communication. In Figure 3 node 13 sends for example a wake-up signal to node 12, which forwards the wake-up to node 11 and so on, until a defined maximum number of forwards, or the destination is reached. Data can then be sent directly from node 13 to one of the woken nodes 10, 11 or 12.

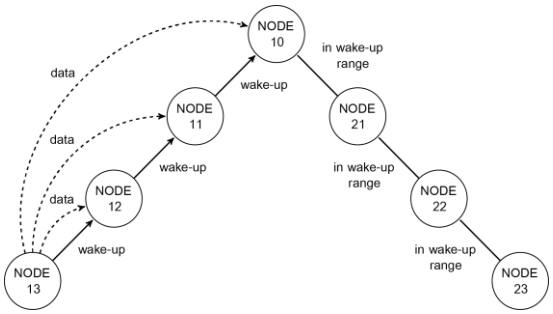

Figure 3: Schematic of the wake-up multi-hop routing protocol developed in this work

Figure 4 shows the sequence diagrams of the routing protocol for the different cases of (a) sending data to a direct neighbour, (b) sending data to a two-hop distant neighbour and (c) sending data to a three-hop neighbour. Decision, to which node data will be sent, is done at the node that started communication by sending a routing request (REQ). The node evaluates the request acknowledges (REQ_ACK) received from the participating nodes (nodes B, C and D). Further nodes are called by forwarding the routing request (FWD_REQ). Implemented parameters to support the decision are: available data slots at the receiving node and hop distance from the starting node. It is possible to include further parameters like link quality, receiver signal strength or remaining energy to increase the stability of the network.

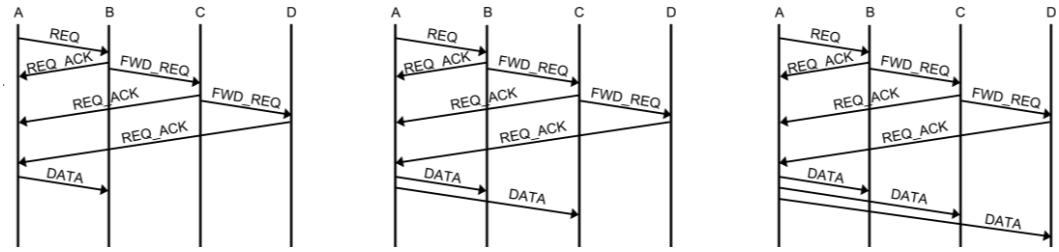

Figure 4: Sequence diagram of the routing protocol for the three different cases of communication to next neighbour (a), two hops neighbour (b) and three hops neighbour (c)

Once the communication link to a node is established, up to 64 data packets consisting of up to 256 bytes size each (max. 16 kB) can be transmitted. After transmission, the link gets closed and the participating nodes fall back to sleep, again. The same routing scheme is repeated until all data reached their destination.

The embedded software is implemented as a state machine as depicted in Figure 5. At the beginning, a sensor node is in SLEEP state in which it consumes only minimal energy. A low-energy timer transfers the node from sleep either to start a sensor measurement (state MEAS), or to check if there is data available in the memory that is not yet sent (state STORE).

In case there are already prepared data slots available, for example from a previously aborted sending, the sleep state will be left and data transfer is initiated by sending a wake-up signal (state SEND WAKE-UP). After a measurement, sensor data is stored in a ringbuffer on the microSD card and data packets are prepared and moved into one of up to 64 available data slots. If there are no free slots available the data is kept in memory to be processed later.

After successful filling the message queue, sending of data is initiated with a wake-up signal (state SEND WAKE-UP). Successfully waking of the neighbour node, is indicated by a wake-up acknowledge and a routing

request is sent (state SEND R_REQ) containing destination ID, number of data packets and max number of wake-up hops. Then, the node listens for route request acknowledgments sent by the woken nodes (state WAIT R_ACK). If at least one node that answers has a free slot available, the node starts to send all possible data packets (state SEND DATA). After successful sending, or if any error occurs, the node exits its current state and goes back to sleep. The state machine of the receiver is similar to that of the transmitter.

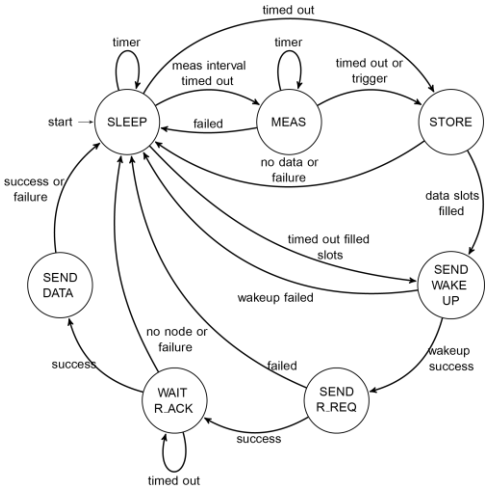

Figure 5: State machine of a sensor node for data transmission

DEPLOYMENT AT THE NECKAR VALLEY BRIDGE WEITINGEN

Figure 6 shows a photo of the Neckar Valley Bridge Weitingen on Highway 81 from Stuttgart to Singen. The bridge is 900 m long and around 127 m above ground at its highest point. The bridge is constructed of five spans and its two end spans consist of inverted cable stay towers that support massive beam spans of 263 m on the southern side and 234 m on the northern side. The locked coil cables are 120 mm and 105 mm thick respectively.

Figure 6: Photo of the Neckar Valley Bridge Weitingen

The upper part of Figure 8 shows schematically the Neckar Valley Bridge in Weitingen. The lower part is a schematic of the first span of the bridge with the deployed WSN during June 2015 including the different kind of sensor nodes. The deployed WSN consisted of several sensor nodes and a base station. The base station (node-10) was placed approximately in the middle of the first span (depicted as blue star in Figure 8). A relay node (node-21/41, green square) was placed near the base station and used to forward data to the base station from sensors farer away. Four sensor nodes (node-22, node-42, node-43 and node-51) were placed inside the box girder at different places (red triangles in lower part of Figure 8). The GNSS receiver was installed at the beginning of the first span (dark-red cross). The antenna was attached to the bridge using a 10 m long cable as can be seen in left side of Figure 7 and as dark-red circle in the schematic. Two tilt sensor nodes (node-23 and node-31, purple circles) were attached to a steel girder, the first approximately in the middle of the first span and the other near the beginning of the bridge. The right side of Figure 7 shows exemplary a photo of deployed node-42 inside the hollow box girder.

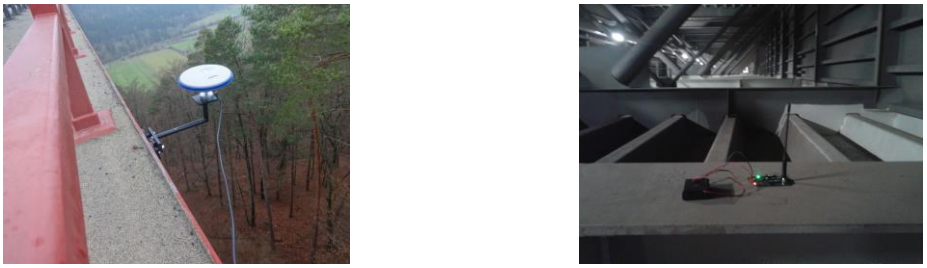

Figure 7: Photo of the GNSS antenna attached to the bridge (left) and a photo of the deployed node-42

This installation was an extension of a previous installation done some days before. The second installation introduced the GNSS receiver node and node-43 which was used to examine the achievable wake-up range inside the hollow box girder. The distance between node-42 and node-43 (two red triangles on the right side) was approximately 125 m, as can be seen in Figure 8. Further focus of this installation was to examine the hard- and software in a realistic environment.

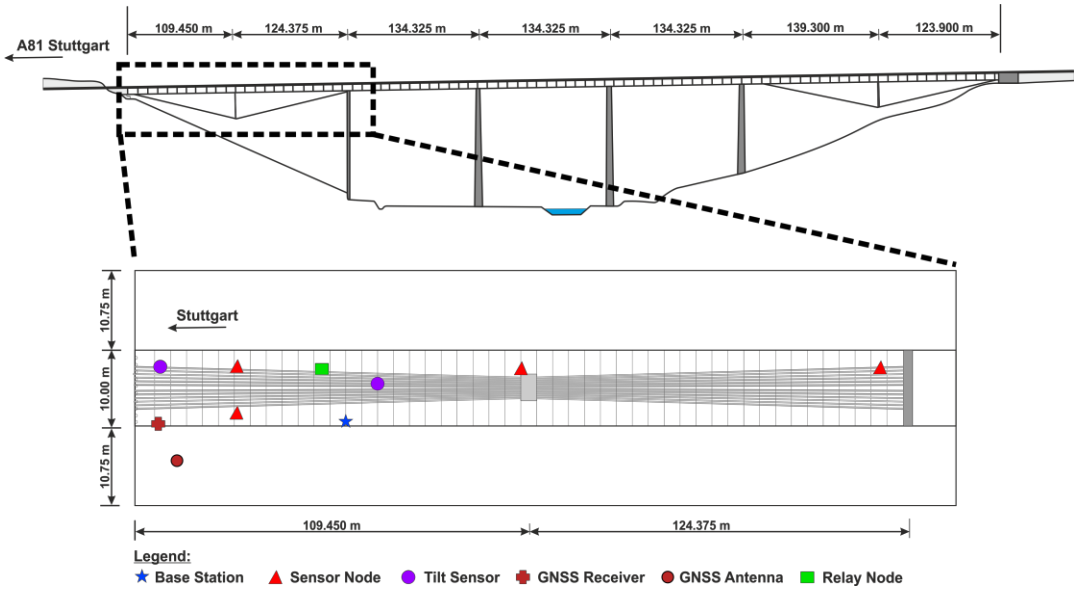

Figure 8: Schematic of the Neckar Valley Bridge Weitingen on the upper half and sensor sodes deployment inside the hollow box girder of the northern span in the lower part

Figure 9 (a) shows the topology of the wake-up network, where each node is able to wake its direct neighbour. Node-43 for example, is in a three hop wake-up distance to the base station, whereas node-52 is in a two hop wake-up distance to the base station. Figure 9 (b) depicts the network topology when all nodes are active. Due to the longer communication range (compared to the wake-up range), additional paths between nodes can be established and the communication hop distances from nodes to the base station can shrink to one hop.

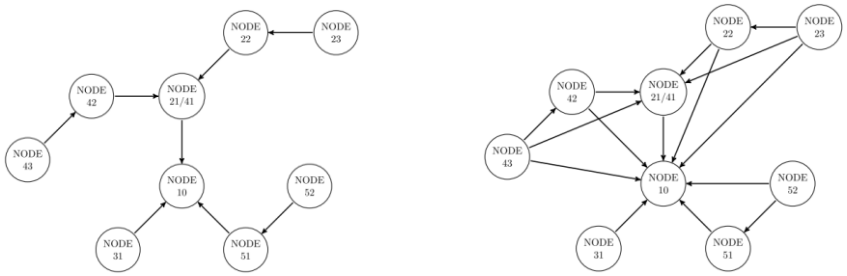

Figure 9: Wake-up network topology (a) and communication network topology (b)

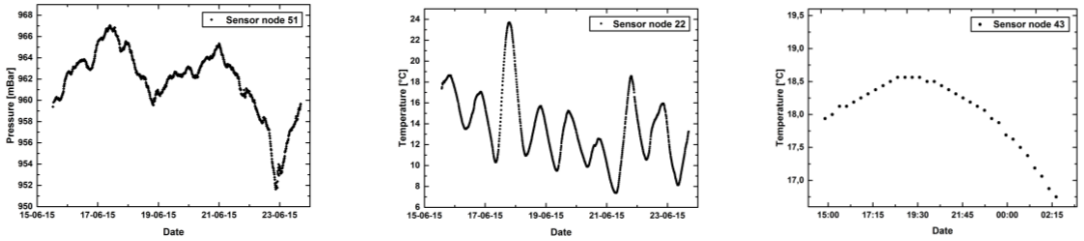
RESULTS

The WSN was installed in June 2015 at the Neckar Valley Bridge Weitingen as introduced in the previous Section. Node-31 and node-51 were sending via a single hop link to the base station, and the others nodes were

linked via a multi-hop connection to the base station. The distance between nodes-42 and -43 was around 125 meters, which is a remarkable distance since the wake-up range in free space is only around 50 m. In our first assumption, this large wake-up range is probably due to the hollow box girder of the bridge that acts in this case as a waveguide for radio signals. The base station successfully transmitted the sensor data to the server in Freiburg at least for a period of one week and still continues to send data during writing of this article, as can be seen in Figure 10 (a) and (b) which show air pressure measured at node-51 and temperature measured at node-22, respectively. Figure 10 (c) shows the temperature readings of node-43 for a period of around 12 hours. After that the sensor stopped sending of data probably due to problems that occurred during a write cycle on the SD-Card.



(a) (b) (c)

Figure 10: Pressure measured at node-51 (a), temperature at node-22 (b) and temperature at node-43 (c)

In this first test run, the GNSS receiver was configured to log at a frequency of 0.1 Hz for a period of 30 minutes every 6 hours. During the time the GNSS receiver node was logging it received 1847 observations, 40 navigation, 44 Glonas navigation and 32 Ionospheric correction messages in total. Figure 11 shows the skyplot of the receiver where it received data from 9 satellites. The GNSS data was visualized with RTKNAVI version 2.4.2

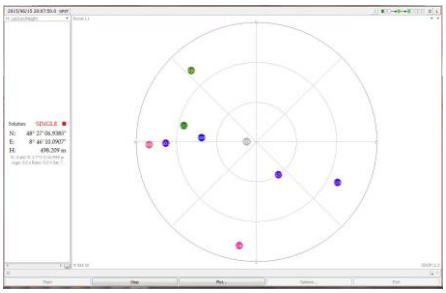


Figure 11: Skyplot from the GNSS data of node-52 visualized with RTKNAVI 2.4.2

CONCLUSIONS

In this article, we introduce low power wireless sensor nodes with integrated wake-up transceiver. Due to their powerful microprocessor the nodes are very flexible and can be equipped with different kinds of sensors for structural health monitoring. In combination with wake-up receivers, the nodes achieve very low power consumption and support different features, such as asynchronous measurements, distribution of important detections with low latency, or pulling of data from the network at any time. Further on, we introduce a routing protocol that supports wake-up receivers and combines them with the advantages of long-range communication radios. A prototype sensor network consisting of several sensor nodes, a base station and a remote server has been installed and tested at the Neckar Valley Bridge Weitingen south-west Germany in June 2015. A Global Navigation Satellite System (GNSS) receiver node was introduced and tested in combination with the wake-up WSN which utilizes the wake-up multi-hop routing protocol as introduced in this work. The setup was running for at least 10 days and is still sending data during time of writing of this article. A base station continuously transmits sensor data to a remote server at the University of Freiburg. To optimize the resolution and the dynamical behaviour of the GNSS data analysis, enhance the network will be further enhanced by additional GNSS receiver nodes in the near future. To improve the overall performance of the network, its long-term stability will be improved by using smart software routines that are able to cope with broken hardware components. In addition we will focus and the development of a dynamic routing protocol to enable easy integration of nodes into an existing network and on the development of a database on the server to analyse and visualize the data.

ABSTRACT

The influencing factors on the evaluation of concrete dam safety are rather complex, which can be divided into quantitative indexes and qualitative indexes and has the characteristic of fuzziness and uncertainty. Expert diagnosis provides positive effect in the comprehensive evaluation of concrete dam safety, and the evaluation result rely on the experiences and wisdom of experts. The importance analysis of experts in the safety evaluation of concrete dams was performed to have fine evaluation result. Subjective expert important analysis model and objective expert importance model were established, and then the interactive objectivity and subjectivity importance analysis model was established. In the end, there proposed models were performed in the safety evaluation of a concrete dam, and the models were verified to be effective in the importance analysis of experts in the evaluation of concrete dam safety.

KEYWORDS

Concrete dam safety, diagnosis indexes, expert diagnosis, objective expert importance, subjective expert importance, interactive expert importance.

INTRODUCTION

The monitoring data and monitoring models are often used to analyze the health status of concrete dams (Zhao 1999; Gu 2008; Zhang 2008; Dai 2014; Li 2015). Due to the complexity of concrete dam, these methods may be not sufficient. Expert diagnosis provides important effect in the comprehensive safety evaluation of concrete dam, and the evaluation result is closely related to the experience and wisdom of experts. Since the experts have different ability, background and experience, the expert weight should be pay attention. The methods to determine expert weight are divided into subjective expert importance analysis and objective expert importance analysis. The subjective expert importance analysis depends on the experts' evaluation, and the objective expert importance analyses relates to their academic status, professional title, practical experience, etc. In this work, subjective expert importance analysis model and objective expert importance analysis model were studied. On this basis, the interactive objective and subjective importance analysis model was obtained. Then the three models were performed in the safety evaluation of a concrete dam, and the models were verified to be effective in the importance analysis of expert diagnosis in the safety evaluation of concrete dam.

THE SUBJECTIVE EXPERT IMPORTANCE ANALYSIS

The influence factors on dam safety include hydrology, geology, design, construction, operation, etc. which make it difficult to determine the importance of the diagnostic indexes (Haiqing 2002; Zhou 2009). By dividing the health diagnosis of concrete dam into several levels and several factors, analytical hierarchy process (Saaty 1980) and fuzzy mathematics (Zhi Jiang 2003) were adopted to quantify the qualitative analysis, and the main procedures were given as follows (Saaty 1980):

（1）Multi influencing factors were decomposed to form the recursive structure.

（2）Set up the judgement matrix

By comparing the diagnosis indexes in one level with that in the upper level, the judgement matrix $R = (\mathrm{r}_{ij})_{m\times m}$ was obtained, and r_{ij} is the importance degree which diagnosis index u_i relative to diagnosis index u_j .

Table 1 The improved '0.1-0.9' scale method

Meaning	Index B is more important than index A	Index B is slightly more important than index A	Index B is equally important to index A	Index A is slightly more important than index B	Index A is more important than index B
Value	0.1	0.3	0.5	0.7	0.9

In the monitoring program of concrete dam, if index A is extremely important than index B, there is no need to set index B. The improved '0.1-0.9' scale method shown in Table.1 was adopted to set up the judgement matrix. Element r_{ij} means the importance degree that index u_i relative to index u_j, which is equally to $1-r_{ji}$. Since elements in the judgement matrix R meet the following condition:

$$0<(r_{ij})_{m\times m}<1 \tag{1}$$

Then matrix $R=\left(r_{ij}\right)_{m\times m}$ is the fuzzy complementary judgment matrix.

(3) Consistency check of the judgement matrix

By calculating the largest eigenvalue $\lambda_{\max}$ of matrix R and the corresponding unit eigenvector $L=[l_1,l_2,\cdots,l_m]$, then consistency ratio $C.R$ was calculated as follows:

$$C.R=\frac{C.I}{R.I},C.I=\frac{\lambda_{\max}-m}{m-1} \tag{2}$$

where $C.I$ is the consistency index and $R.I$ is the average random consistency index of the judgement matrix R.

The values of $R.I$ are listed in Table.2.

Table 2 The average random consistency index

m	1	2	3	4	5	6	7	8	9
R.I	0.00	0.00	0.52	0.89	1.12	1.26	1.36	1.41	1.46

If the consistency ratio C.R is smaller than 0.1, judgement matrix R is deemed to have satisfying consistency, otherwise, judgement matrix R was modified according to the following equations to have the satisfying consistency.

$$\bar{r}_i=\sum_{j=1}^{m}r_{ij},\ \bar{r}_{ij}=\frac{\bar{r}_i-\bar{r}_j}{\alpha}+0.5\quad i,j=1,2,\cdots,m;\quad \alpha\geq 2(m-1) \tag{3}$$

Based on fuzzy mathematics, we demonstrate that matrix $\bar{A}=\left(\bar{r}_{ij}\right)_{m\times m}$ is the fuzzy consistent judgement matrix.

(4) Calculate the importance vector

For the fuzzy consistent judgement matrix, the subjective importance vector of the i th diagnosis index was obtained:

$$w_i^s=\sum_{j=1}^{m}\bar{r}_{ij}\Big/\sum_{i=1}^{m}\sum_{j=1}^{m}\bar{r}_{ij} \tag{4}$$

Considering that the fuzzy consistent matrix meets the following condition:

$$r_{ij}+r_{ji}=1,\sum_{i=1}^{m}\sum_{j=1}^{m}r_{ij}=\frac{m^2}{2} \tag{5}$$

Then

$$w_i^s=\frac{2}{m^2}\sum_{j=1}^{m}\bar{r}_{ij} \tag{6}$$

If the judgement matrix is not the fuzzy consistent matrix, translation was achieved through equation (3), and we obtain:

$$\begin{aligned}w_i^s&=\frac{1}{m}+\frac{2}{\alpha m}\sum_{j=1}^{m}r_{ij}-\frac{2}{\alpha m^2}\sum_{j=1}^{m}\bar{r}_j=\frac{1}{m}+\frac{2}{\alpha m}\sum_{j=1}^{m}r_{ij}-\frac{2}{\alpha m^2}\sum_{i=1}^{m}\bar{r}_i\\&=\frac{1}{m}+\frac{2}{\alpha m}\sum_{j=1}^{m}r_{ij}-\frac{2}{\alpha m^2}\sum_{i=1}^{m}\sum_{j=1}^{m}r_{ij}=\frac{1}{m}-\frac{1}{\alpha}+\frac{2}{\alpha m}\sum_{j=1}^{m}r_{ij}\end{aligned} \tag{7}$$

THE OBJECTIVE EXPERT IMPORTANCE ANALYSIS

To consider the different social environment, experience, education background and professional familiarity of experts, the objective expert importance was divided into prior expert importance and posterior expert importance. Prior expert importance relates to the experience, education background and professional familiarity of experts, and posterior expert importance relates to the departure degree between the judgement matrix of experts and the comprehensive evaluation matrix.

The Prior Expert Importance

To have more accurate safety evaluation of concrete dam, the experts with great ability or popularity were given greater weight, and the experts with poor ability and low popularity were given small weight. As shown in Fig.1, the prior importance indexes of experts were divided into rigid indexes and soft indexes, and the items such as position, education background, job titles, published papers, citations, prizes, done programs, academic conferences, knowledge structure, practical experience, familiarity degree of the subject were included. Table.3-Table.6 illustrates the evaluation criteria of the prior expert importance. The m evaluation indexes of n experts was given scores, and the scores vector of the i th expert was $x_i = (x_{i1}, x_{i2}, \cdots, x_{im})$, $(i = 1, 2, \cdots, n)$. Then the scores evaluation matrix is

$$X = (x_{ij})_{n \times m} \tag{8}$$

where x_{ij} is the score of the j th index given by the i th exper.

Grade	Criterion	Score	Grade	Criterion	Score	Grade	Criterion	Score
1	Very proficient	50	1	Do the health diagnosis frequently	50	1	Very familiar	50
2	Relatively proficient	35	2	Has done the health diagnosis	35	2	Relatively familiar	35
3	General understanding	20	3	Has done the related work	20	3	Generally familiar	20
4	Relatively narrow	10	4	Do not done any work	10	4	Not familiar	10

The scores evaluation matrix was linearly transformed to be the matrix in which the interval of the quantized value is 0~1:

$$r_{ij} = \frac{x_{ij}}{x_{\max j}} \quad (i = 1,2,\cdots,n;\ j = 1,2,\cdots,m) \tag{9}$$

where $x_{\max j}$ is the maximum score in the j th index of the experts.

To reflect the normalized scores evaluation matrix $R = (\mathrm{r}_{ij})_{n\times m}$ as much as possible and evaluate the importance degree of the experts, the prior importance analysis model based on the dominance least included angles method was built up, and it was transformed as follows:

$$d_{ij} = r_{ij}^{k} \Big/ k^{k-1}, \quad (i = 1,2,\cdots,n;\ j = 1,2,\cdots,m;\ k = 1,2,\cdots,m-1) \tag{10}$$

where matrix $D = (d_{ij})_{n\times m}$ is the dominance matrix and d_{ij} is the m-step dominance.

The prior importance vector of n experts was $w = (w_1, w_2, \cdots, w_n)^T$, and the scores vector is $d_j = (d_{1j}, d_{2j}, \cdots, d_{nj})^T$, $(j = 1,2,\cdots,m)$.

The sum of the included angle cosine $S = \sum_{j=1}^{m} \cos\theta_j$ should be big enough to reflect vector w^1, where θ_j is the included angle between w and d_j. Through the adoption and solution of nonlinear problem as follows:

$$\begin{cases} \max \quad F(w)=\sum_{j=1}^{m} d_j^T w=\sum_{i=1}^{n}\sum_{j=1}^{m} d_{ij} w_i \\ s.t \quad \sum_{i=1}^{n} w_i^2=1, \quad w>0 \end{cases} \tag{11}$$

We obtain $w_i^*=\sum_{j=1}^{m} d_{ij} \Big/ \sqrt{\sum_{i=1}^{n}(\sum_{j=1}^{m} d_{ij})^2}$, and $w^*=(w_1^*, w_2^*, \cdots, w_n^*)$ was normalized as follows:

$$w_i^1=w_i^* \Big/ \sum_{i=1}^{n} w_i^*, (\mathrm{i}=1,2,\cdots,n) \tag{12}$$

where w_i^1 is the prior importance value of the i th expert.

The Posterior Expert Importance

The posterior expert importance relates to the experts' predilection, the consistency of logical judgement of experts and the compatibility between the individual judgement and the comprehensively judgement of the expert groups.

The fuzzy judgement matrix with consistency demonstrates that experts have strong logical thinking ability; rather, the fuzzy judgement matrix without consistency indicates its poor credibility, imprecise logical thinking ability and weak importance, and the judgement matrix R was modified according to equation (3) to be fuzzy consistency matrix.

The consistency of the comprehensive matrix of the expert groups relates to both the consistency of the individual expert and the boundedness of the scale methods of the judgement matrix. If the importance judgement matrix of an expert is highly compatible with the comprehensive matrix, the evaluation of the expert was considered to have high accuracy. Otherwise, the diagnosis of the expert was not compatible with the most experts.

After adjusting the judgement matrix into the fuzzy consistency matrix, the importance judgement which the k th expert evaluates on the diagnosis indexes is $(\mathrm{r}_{ij}^k)_{m\times m}$. The comprehensive fuzzy judgement matrix based on the fuzzy judgement of the experts is $R^*=(r_{ij}^*)_{m\times m}$. The smaller the distance between the fuzzy judgement matrix which the k th expert evaluates and the comprehensive fuzzy judgement matrix is, the judgement of the expert is closer to the comprehensive judgement.

In the norm of matrix theory, the distance between the k th expert and the comprehensive matrix was given as follows:

$$d_k=\left\| R^k-R^* \right\| \tag{13}$$

The consistency degree between the individual judgement matrix R^k and the comprehensive judgement matrix R^* is the distance $d=(R^k, R^*)$ between the two matrix. Then the compatible importance vector of the expert groups was obtained:

$$w_i=(w_1, w_2, \cdots, w_n)=(\sum_{k=1}^{n} d_k-d_k) \Big/ \sum_{k=1}^{n} d_k \tag{14}$$

By normalizing the importance vector of the expert groups, the posterior importance value of each expert was:

$$w_i^2=w_i \Big/ \sum_{i=1}^{n} w_i \tag{15}$$

The Objective Expert Importance

Since the prior expert importance and the posterior expert importance have equally influence on the objective expert importance, the arithmetic mean method was adopted to obtain the objective expert importance:

$$w_i^o=(w_i^1+w_i^2)/2 \tag{16}$$

where w_i^o is the objective expert importance, w_i^1 is the prior expert importance, w_i^2 is the posterior expert

importance.

THE INTERACTIVE OBJECTIVITY AND SUBJECTIVITY EXPERT IMPORTANCE ANALYSIS

Based on the subjective expert importance analysis and the objective expert importance analysis, the interactive objective and subjective expert importance analysis was performed.

Suppose n experts were invited to evaluate the diagnosis set $U=\{u_1,u_2,\cdots,u_m\}$ which consists of m diagnosis indexes, the subjective importance vector which the i th expert evaluates on the diagnosis indexes was:

$$w_i^s=(w_{i1}^s,w_{i2}^s,\cdots,w_{im}^s) \tag{17}$$

Then the subjective expert importance matrix which n experts evaluate on the m diagnosis indexes was:

$$W^s=\begin{bmatrix} w_{11}^s & w_{12}^s & \cdots & w_{1m}^s \\ w_{21}^s & w_{22}^s & \cdots & w_{2m}^s \\ \vdots & \vdots & \vdots & \vdots \\ w_{n1}^s & w_{n2}^s & \cdots & w_{nm}^s \end{bmatrix} \tag{18}$$

The objective importance vector of n experts was $(w_1^o,w_2^o,\cdots,w_n^o)$.

Then the subjective expert importance was modified through the objective expert importance to obtain the interactive expert importance:

$$W=[W_1,W_2,\cdots,W_m]=[w_1^o,w_2^o,\cdots,w_n^o]\cdot\begin{bmatrix} w_{11}^s & w_{12}^s & \cdots & w_{1m}^s \\ w_{21}^s & w_{22}^s & \cdots & w_{2m}^s \\ \vdots & \vdots & \vdots & \vdots \\ w_{n1}^s & w_{n2}^s & \cdots & w_{nm}^s \end{bmatrix} \tag{19}$$

CASE STUDY

Mianhuatan concrete dam was taken to have health diagnosis, and four levels of diagnosis indexes system was built up as shown in Fig.2. The subsystem of monitoring behavior was evaluated by four experts, and the subjective expert importance analysis was used to determine the importance of the diagnosis indexes as follows:

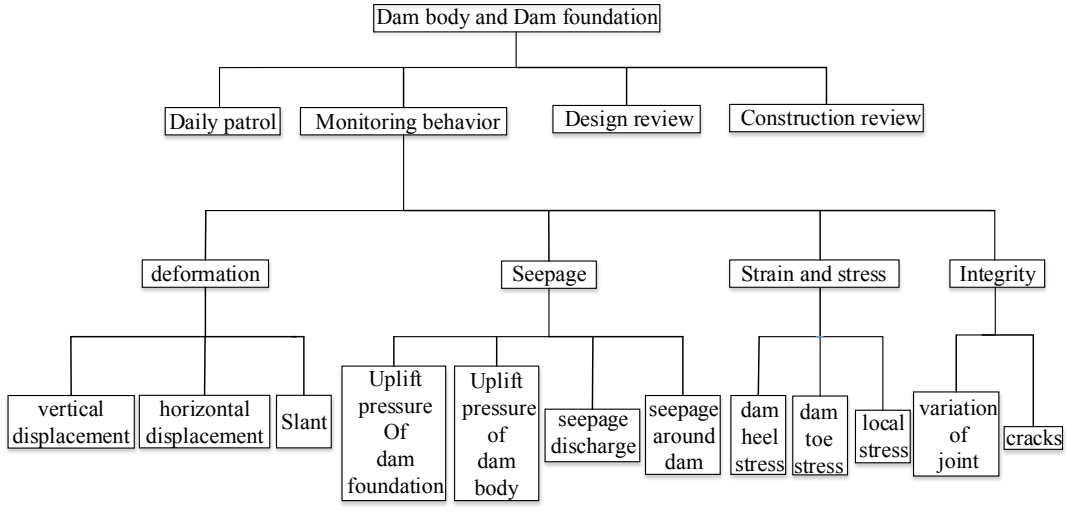

Figure 2 the four levels of diagnosis indexes system of Mianhuatan concrete dam

$$A=\begin{bmatrix}0.5 & 0.5 & 0.7 & 0.6\\ 0.5 & 0.5 & 0.8 & 0.7\\ 0.3 & 0.2 & 0.5 & 0.4\\ 0.4 & 0.3 & 0.6 & 0.5\end{bmatrix}, B=\begin{bmatrix}0.5 & 0.4 & 0.7 & 0.6\\ 0.6 & 0.5 & 0.7 & 0.7\\ 0.3 & 0.3 & 0.5 & 0.4\\ 0.4 & 0.3 & 0.6 & 0.5\end{bmatrix}$$

$$C=\begin{bmatrix}0.5 & 0.4 & 0.6 & 0.6\\ 0.6 & 0.5 & 0.7 & 0.7\\ 0.4 & 0.3 & 0.5 & 0.5\\ 0.4 & 0.3 & 0.5 & 0.5\end{bmatrix}, D=\begin{bmatrix}0.5 & 0.6 & 0.7 & 0.6\\ 0.4 & 0.5 & 0.6 & 0.5\\ 0.3 & 0.4 & 0.5 & 0.4\\ 0.4 & 0.5 & 0.6 & 0.5\end{bmatrix}$$

where A, B, C, D mean the Expert A, B, C, D, respectively.

The fuzzy consistent judgement matrixes were obtained by adjusting the judgement matrixes according to equation (3) as follows:

$$A'=\begin{bmatrix}0.500 & 0.467 & 0.650 & 0.583\\ 0.533 & 0.500 & 0.683 & 0.617\\ 0.350 & 0.317 & 0.500 & 0.433\\ 0.4174 & 0.333 & 0.567 & 0.500\end{bmatrix}, B'=\begin{bmatrix}0.500 & 0.450 & 0.617 & 0.567\\ 0.550 & 0.500 & 0.667 & 0.617\\ 0.383 & 0.333 & 0.500 & 0.450\\ 0.433 & 0.383 & 0.550 & 0.500\end{bmatrix}$$

$$C'=\begin{bmatrix}0.500 & 0.43 & 0.567 & 0.567\\ 0.567 & 0.500 & 0.633 & 0.633\\ 0.433 & 0.367 & 0.500 & 0.500\\ 0.433 & 0.367 & 0.500 & 0.500\end{bmatrix}, D'=\begin{bmatrix}0.500 & 0.567 & 0.633 & 0.567\\ 0.433 & 0.500 & 0.567 & 0.500\\ 0.367 & 0.433 & 0.500 & 0.433\\ 0.433 & 0.500 & 0.567 & 0.500\end{bmatrix}$$

The parameter α was set as $2(m\text{-}1)$ to decrease the influence of the selection of parameters on the judgement matrix, and the importance value w was calculated as follows:

$$w_i=\frac{1}{m}-\frac{1}{2(m-1)}+\frac{1}{\mathrm{m}(m-1)}\sum_{j=1}^{m}r_{ij} \tag{20}$$

The subjective expert importance of diagnosis indexes are calculated as follows:

Table 7 the subjective importance of diagnosis indexes for the four experts

Subjective importance	Deformation	Seepage	Strains and stress	Integrity
A	0.275	0.292	0.200	0.233
B	0.267	0.295	0.208	0.233
C	0.258	0.292	0.225	0.225
D	0.283	0.250	0.217	0.250

Then we calculate the objective expert importance. Based on the dominance least included angles method, the reliability of expert evaluation was judged with the scores listed in Table.8.

Table 8 the subjective importance of diagnosis indexes for the five experts

Scores	Position	Education background	Job titles	Done programs	Prizes	Academic conferences
Expert A	20	20	35	20	10	10
Expert B	35	50	20	35	35	35
Expert C	10	35	50	35	20	20
Expert D	10	35	35	20	20	20
Scores	Knowledge structure	Practical experience	Familiarity degree of the subject	published papers	numbers of citations	criterion of citations
Expert A	10	20	35	30	25	40
Expert B	50	35	50	30	35	40
Expert C	20	10	35	45	40	45
Expert D	10	35	35	35	30	35

After the transition based on the equations (9) and (10), the dominance matrix was obtained as shown in Table.9.

Table 9 the dominance matrix of the experts' evaluation values

A	0.163	0.080	0.245	0.163	0.041	0.041	0.020	0.163	0.245	0.222	0.195	0.395
B	0.500	0.500	0.080	0.500	0.500	0.500	0.500	0.500	0.500	0.222	0.383	0.395
C	0.041	0.245	0.500	0.500	0.163	0.163	0.080	0.041	0.245	0.500	0.500	0.500
D	0.041	0.245	0.245	0.163	0.163	0.163	0.020	0.500	0.245	0.302	0.281	0.302

Then the prior importance values of the four experts were calculated as follows:

$$W^1 = (w_1^1, w_2^1, w_3^1, w_4^1) = (0.150, 0.385, 0 \quad (21)$$

For the posterior importance of the experts, we should judge the logical judgement ability of the experts. After transforming the judgement matrix which the four experts evaluate on the four diagnosis indexes based on equation (3), the four experts were considered to have relatively strong logical judgement ability and the same importance of the experts, which have the equally influence on the posterior importance. Then the group compatibility should be emphasized. Based on the prior importance values, the comprehensive fuzzy judgement matrix was obtained:

$$R^* = \begin{bmatrix} 0.500 & 0.472 & 0.612 & 0.569 \\ 0.528 & 0.500 & 0.640 & 0.598 \\ 0.388 & 0.360 & 0.500 & 0.457 \\ 0.431 & 0.402 & 0.543 & 0.500 \end{bmatrix} \quad (22)$$

The posterior importance of the four experts was as follows:

$$W^2 = (w_1^2, w_2^2, w_3^2, w_4^2) = (0.272, 0.311, 0 \quad (23)$$

The prior importance and posterior importance were considered to have equally influence on the objective importance, therefore the objective importance of the experts was obtained:

$$(w_1^o, w_2^o, w_3^o, w_4^o) = (W^1 + W^2)/2 = (0.211, 0.348, 0.258, 0.183) \quad (24)$$

Based on equation (19), the interactive expert importance was calculated as follows:

$$\begin{aligned} W &= [W_1, W_2, W_3, W_4] = \left[w_1^o, w_2^o, w_3^o, w_4^o \right] \cdot \begin{bmatrix} w_{11}^s & w_{12}^s & w_{13}^s & w_{1m}^s \\ w_{21}^s & w_{22}^s & w_{23}^s & w_{24}^s \\ w_{31}^s & w_{32}^s & w_{33}^s & w_{34}^s \\ w_{41}^s & w_{42}^s & w_{43}^s & w_{44}^s \end{bmatrix} \\ &= [0.211, 0.348, 0.258, 0.183] \cdot \begin{bmatrix} 0.275 & 0.292 & 0.200 & 0.233 \\ 0.267 & 0.295 & 0.208 & 0.233 \\ 0.258 & 0.292 & 0.225 & 0.225 \\ 0.283 & 0.250 & 0.217 & 0.250 \end{bmatrix} \\ &= [0.269, 0.285, 0.212, 0.234] \end{aligned} \quad (25)$$

For Mianhuatan concrete dam, the time-effect displacements are almost steady and the change rules of both horizontal displacement and vertical displacement are normal. Since the deformation monitoring is the most intuitive and effective reflection of the monitoring behavior of the dam, the analysis of the deformation monitoring data is adequate for a long time and the monitoring accuracy is relatively high. Therefore the deformation monitoring has relatively larger importance in the whole diagnosis indexes.

The seepage monitoring has the characteristic of intuition and could reflect the operation status of the dam under the effect of various loads. Moreover, the seepage state plays more important role in reflecting the safety status of the dam foundation. In fact, the foundation of Mianhuatan concrete dam is rather complex and the effect of the curtain grouting is not good. The uplift pressure in some places of the foundation is abnormal and the underground water has the erosion effect on the concrete. These factors make the situation that the seepage is more important than other monitoring programs.

The stress and strain monitoring belongs to the introspection, which provide reference for the designs and

construction. However, the monitoring accuracy of stress and strain is not good. Hence, the importance degree of stress and strain is lower than seepage monitoring and deformation monitoring.

The integrity is an important aspect which reflects the operation status of the dam. The monitoring of joints and cracks could immediately reflect the safety status of the dam. However, the monitoring of joints and cracks are not systematically, the development trend of the cracks is difficult to make judgement, the mechanical analysis method could provide help. Hence, the importance degree of integrity of dam is lower than deformation monitoring and seepage monitoring, and it is slightly more important than stress and strain monitoring.

Based on the practical analysis of the Mianhuatan concrete dam, the research methods are verified, which could provide reference for the overall evaluation of the concrete dam based on the expert diagnosis.

CONCLUSIONS

The safety evaluation of concrete dam based on the expert diagnosis indexes was studied in this paper. Based on the characteristic of fuzziness and uncertainty on the safety evaluation of concrete dam and the characteristic of experts' diagnosis, subjective expert importance analyses, the objective importance analysis and the interactive objectivity and subjectivity expert importance analysis were studied. Through the practical analysis of Mianhuatan concrete dam, the proposed methods were verified to provide reference for the overall evaluation of concrete dam based on the expert diagnosis.

ABSTRACT

This paper introduces suitable features and methods to define hazard rate function by acoustic emission parameters to develop robust damage statement index and reliability analysis. AE signal energy was first examined to find out relation between damage progress and AE signal energy so that a damage index based on AE signal energy was proposed to quantify progressive damage imposed to composite slabs. Moreover by using AE signal strength, historic index was utilized to develop a modified hazard rate function through integration bathtub curve and Weibull function.

KEYWORDS

Acoustic emission; bathtub curve, damage detection; reliability analysis, ferrocement slabs; failure analysis

INTRODUCTION

Multi-layers ferrocement composite slab is considered as a recognized composite structure with an ever-increasing attraction because of their cost effectiveness, raw material availability, easily fabrication and installation where shapes and forms are complex. Inherent physical properties of ferrocement provide a refined material which shows proper resistance against shrinkage, cracking, and usually possesses high level of ductility (Cheah & Ramli, 2012). However, life time safe performance of composite structures is in a great demand while the complex inherent characteristic of these structures requires rigorous measures to be taken. Hence, Diagnosis and monitoring techniques are progressively imperative for evaluating structural reliability assessment, and one possible application may suggest structural damage diagnosis and reliability analysis for composite structures (Farhidzadeh et al., 2014).

Acoustic emission (AE) has been appearing as a potential technique to be deployed for online structural health monitoring and diagnosis purposes (Behnia et al. 2014a). The premise of AE refers to the generation of transient elastic waves during the rapid release of energy from a localized source within a material. The fundamental concept of AE brings some unique features for this technique as an applicable non-destructive testing technique. Among these features the most important ones are (1) real time capability, (2) high sensitivity, (3) global monitoring capability, (4) source location, (5) sensitivity to any process or mechanism that generates stress waves, (6) passive nature (no need to supply energy from outside, but energy from damage source itself is utilized) (Behnia et al. 2014b).

However, potential capability of AE as an informative online assessment technique offers opportunity to increase utilization of AE technique in different types of structures with variety purposes. AE was used in localization of damage in composite and RC structures (Bagherifaez et al., 2014), crack detection (Iliopoulos et al., 2015) damage assessment (Carpinteri & Lacidogna, 2007) corrosion, fatigue, creep, fracture modes analysis, durability (Abdelrahman et al., 2014; Carpinteri et al., 2013; Kawasaki et al., 2013 . Aggelis et al., 2013; Farhidzadeh et al. 2013; Aggelis et al., 2014).

To the best of the authors' knowledge, although there are many extensive studies carried out on application of AE for different structures, there are a few studies, if any, developing robust method to extract suitable AE features in order to perform failure reliability analysis and to extract damage sensitive features. Considering the capability of statistical techniques in addressing un-certainty quantitatively, structural damage detection can benefit from utilizing statistical techniques in complex composite structures. Therefore, the principal objective of this study is twofold: First, introducing suitable features and method to obtain hazard rate function by AE parameter and Second, extraction sensitive feature to develop robust damage statement index.

Materials and Instrumentation of Experiments and AE Sensors

Locally sourced ASTM Type I Portland Cement (PC) was used as the key binder material. Low calcium fly ash (class F) used in this research was supplied by Lafarge Malayan Cement Bhd, Malaysia. Due to the round particle shape and high silica content, incorporation of fly ash has the potential to reduce the water demand, enhance the workability of the fresh matrix and improve the hydration process of Portland cement. Locally available river sand with grading in accordance with the limit values specified by BS882 was used as an aggregate for the mortar mixes. The river sand was washed prior to mixing to remove the natural silt and clay in the raw stock pile.

Steel moulds with open top and bottom faces with dimensions of 500 mm*500 mm* 30 mm were used. For each slab specimen, a thin layer of mortar was initially poured to achieve the desired cover thickness before the wire mesh was positioned in the slab over the mortar layer.

The mortar has been evenly spread into the reinforcement network. In the last step, to ensure the smooth top surface, the finishing step was performed on the top by levelling a thin layer of mortar. The specimens were left for 24 hours to set after casting. The testing machine and schematic detail of the test procedure is given in Figure 1.

The AE measurement system adopted in the experimental study consisted of PCI-2 data acquisition boards (by Mistras Group Inc) that accommodate a total of six AE sensors and a Windows-based AE data operation program known as AEwin. The AE sensors used have a resonant excitation frequency of 60 kHz (R6I). A total of six sensors were mounted on the specimens. In the measurements, the sampling rate for AE monitoring was set to 2 MHz with the pre-trigger set to 250μs. The hit definition time (HDT), hit lockout time (HLT), and wave velocity were configured as 2000 μs, 300 μs and 3900 m/s, respectively. To eliminate electrical and mechanical noise, the threshold level of acquisition was set at 50 dB.

Figure 1 Test setup and flexural strength test of ferrocement composite slab and AE sensor placement

RESULTS

Mechanical Behavior of Composite Slab and Its Correlation to AE

Figure 2a and 2b presents the typical failure patterns for composite slabs. In general, two types of failure patterns were registered for specimens. Composite slabs with four layers of wire meshes, called S4, failed in flexural failure mode, whereas composite slabs with six layers of wire meshes, called S6, failed in punching failure mode. As the load increased, new cracks were formed and existing cracks propagated slightly in the radial direction. Punching failure was highlighted by a sudden drop in the applied load. As illustrated in Figure 3a, punching shear failure was completely obvious, indicated by the formation of a “hole" on the top face. On the bottom face, on the other hand, an outline of a truncated failure cone was merely noted which had a much larger perimeter than the hole which formed on the top face. On the other hand, when most of the reinforcement yielded prior to failure and the slabs subsequently underwent large deflection and smooth decline of carrying load, the dominant failure mode was flexural failure. In this case, cracks propagated in diagonal direction in the bottom face which is illustrated in Figure 2b.

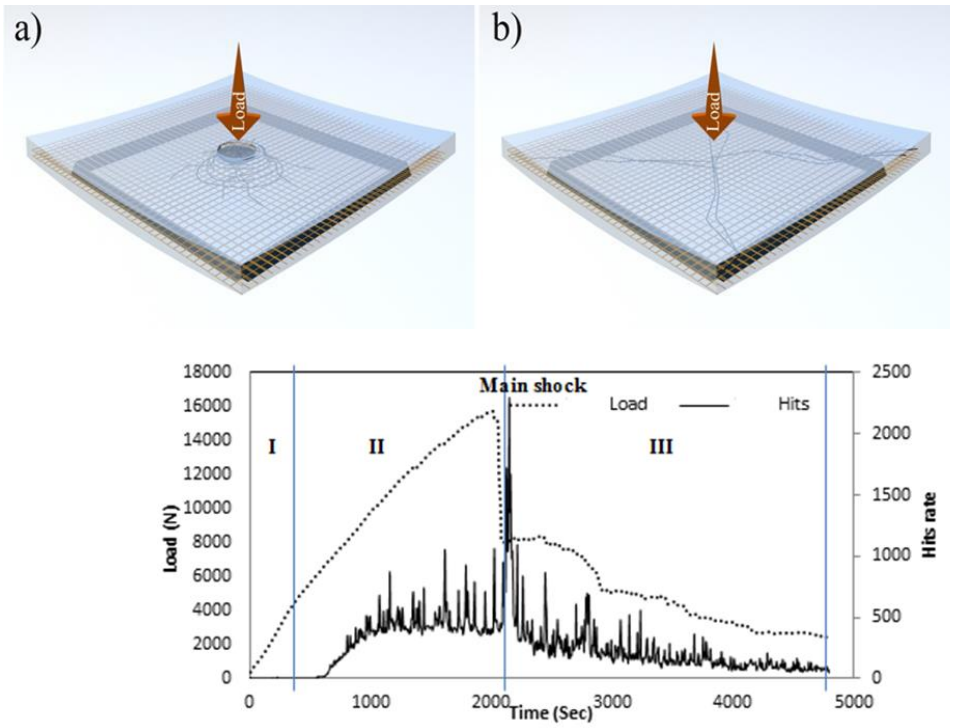

Figure 2 composite slab failure pattern: a) Schematically shear failure, b) Schematically shear failure, c) Load profile versus AE hits rate

Figure 2c presents typical samples for each type of failure mode in terms of the rate of AE hits against loading for these types of slabs, the fracture process starts with micro-cracking stage (I) which is the so-called pre-cracking elastic stage. As can be observed, in this stage the AE activity level is considerably lower than the following stages. Upon the emergence of the first macro-crack/flexural crack in the centre on the bottom side of slab which is highlighted by the reduction in the slope of load-deflection curve, a sudden increase in the AE hit rate was registered. This stage (II) is called post-cracking/multiple cracking or Elasto-plastic cracking regarding the elastic behaviour of this stage after the first nonlinearity. The AE emission rate remained moderate due either to propagation of existing cracks or to the occurrence of new cracks until the peak load at which the punching failure was captured. Punching failure coincided with the main shock of the AE hits rate which is identified by the maximum rate of AE hits. Thereafter, in the post-punching stage (III), a considerable drop in AE hits rate was observed due to significant drop in the loading. In this stage, the tensile reinforcements started to yield. Most AE hits in this stage can be attributed to the crack widening and yielding tensile reinforcement in the form of membrane action of the slab. Hence, yielding of reinforcement results in a low population of AE activity with higher amplitude compared to the previous stages. However, AE hits data could not provide quantitative insight to the damage state of the composite slab. Therefore, two AE parameters, signal strength and AE energy will be explored in next sections.

AE signal energy analysis

From the AE measurement and analysis performed on the AE data, the trend of variation of AE energy with respect to the evolution of damage was investigated. Toward this purpose, the largest AE energy was chosen. According to the energy level of AE hit, all AE hits were categorized into four groups (Classes). There are three selected energy levels through which subsequent classes were formed. The energy levels and associated classes are listed below:

Level 1= 10000 V2µs, Level 2= 100000 V2µs, Level 3 = 1000000 V2µs
Class A = under level 1, Class B= above level 1, Class C= above level 2, Class D = above level 3

The number and percentages of AE events and corresponding AE energy released during the damage process of composite slabs relative to the associated total values are presented in Table 1 and Figure 3. As presented in Table 1 results for both composite slabs (S4 and S6) show that while the number of occurrences of AE events in class A was considerably high, the AE energy released during these AE events were significantly low.

Consequently, it might be inferred that the level of damage pertinent to these AE activities is significantly low. It was observed that in terms of energy level, most AE events belonged to class B.
It means that most of the signals which were emitted during the damage process had energy level greater than 100000 V2µs (Level 2).

Figure 4 presents the AE events source localization for S6 during damage process considering different classes of AE energy levels. As indicated in Figure 4, AE energy level of class C contributed significantly to the fracture process zone while AE energy above Class C (Class D) possessed fairly high acoustic emission energy per unit area of fracture process zone. These observations indicate that AE events with higher energy level than 100000 V2µs predominantly contributed to the fracture process zone because of their high energy level, whereas the total numbers of AE activities were quite low.

In general for all composite slabs, the number of AE event for class A and B was considerably high while these AE events possessed low energy. Conversely, AE events intensity for class C and D were lower while associated AE energies were considerably high especially these events located in fracture zone (punching area). Therefore, in general, it was found that AE energy has great potential trace changes imposed to the structure during the fracture process. In this line, a damage index by using AE energy time history of S6 was extended.

	class D	67	0.97	35212307000	95.61

AE Energy Index

AE energy released during the period of loading was measured from AE acquired data set. Figure 5 displays the history of AE energy rate for a composite slab loading set, and together with history of stiffness variation till ultimate load capacity. It can be observed that loading in the beginning of the test did not trigger the AE energy immediately, but after a while later. It could be because at the early stage of loading the fracture did not happen since the AE energy is attributed to prompt release of energy in a concrete during fracture. In addition, AE energy general trend showed a tendency to rise with increase in loading process and subsequent reduction of specimen's stiffness.

The accumulated AE energy over the consecutive load stages until ultimate load capacity was computed and plotted in Figure 6, superimposed to the total and loss of stiffness values.

Considering the relation between accumulated AE energy and loss of stiffness, an attempt can be put forward to find out a correlation between normalized values of accumulated AE energy and loss of stiffness. The normalized accumulated AE energy and loss of stiffness over successive loading stages were plotted in Figure 7.

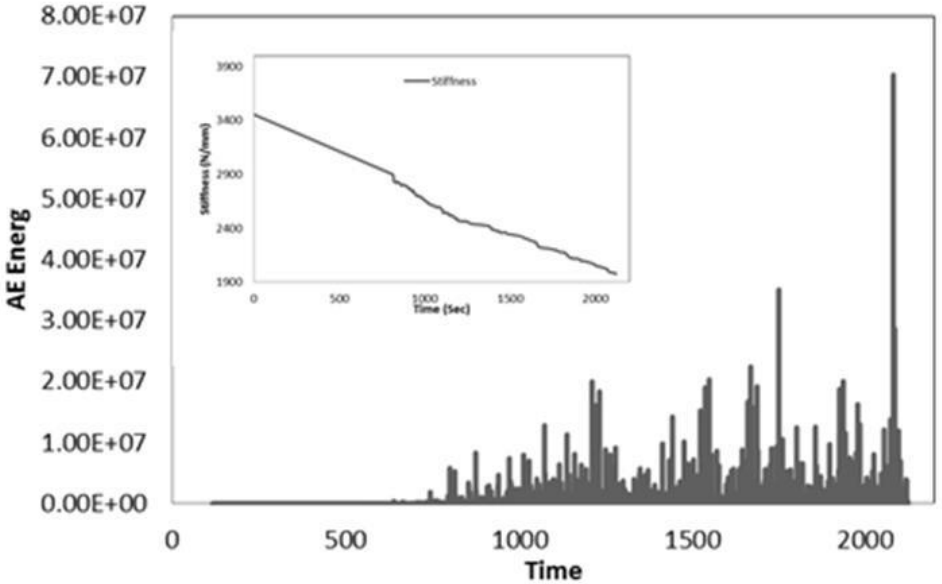

Figure 5 AE energy rate and stiffness variation time history till ultimate load capacity

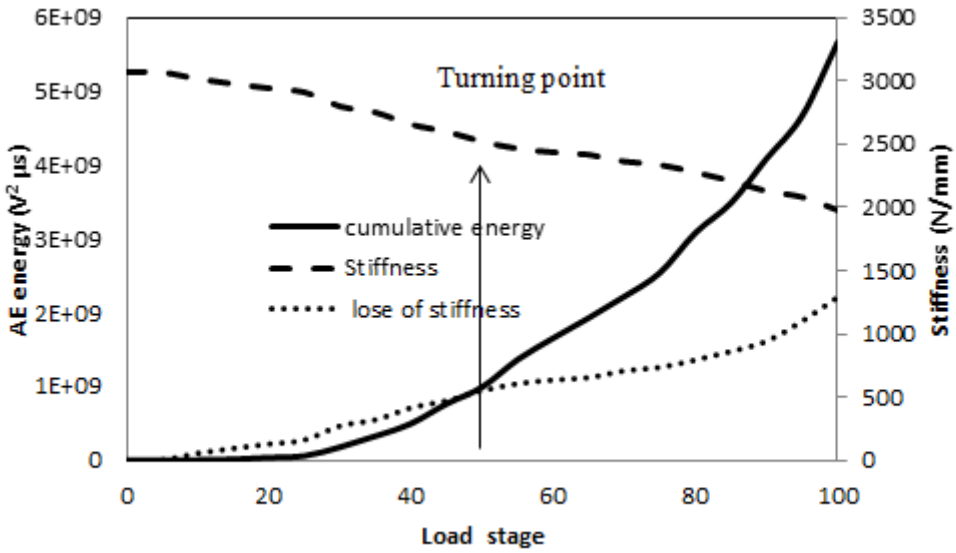

Figure 6 Accumulated AE energy during loading stage till failure and total and loss of stiffness values

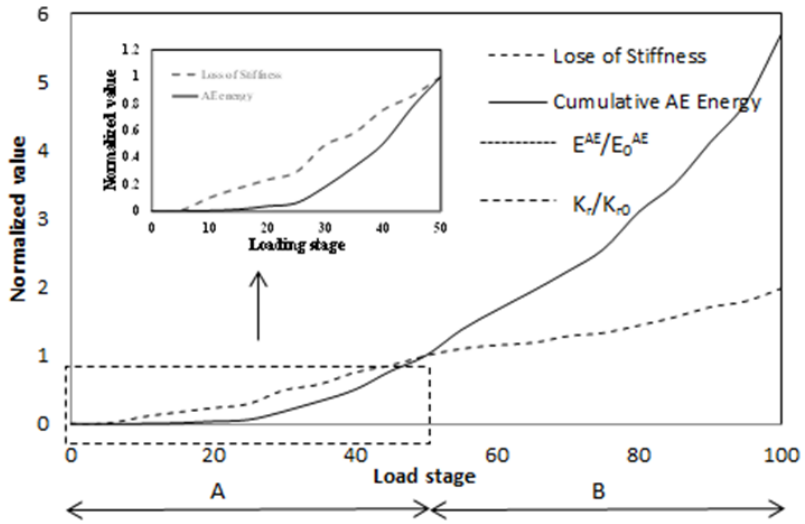

Figure 7 Normalized accumulated AE energy and loss of stiffness at the end of 50% of loading process

A given instant n, E_n^{AE}, was extracted from the entire trend of AE energy and plotted in left top side of Figure 7, superimposed on to the loss of stiffness (K_r/K_{ro}). It should be noted that the AE energy and loss of stiffness were both normalized at the end of 50% loading process where a visible turning point was observed in total stiffness value in Figure 6. AE energy and slab loss of stiffness in each instance were named as E^{AE} and K_r, respectively, whereas AE energy and slab loss of stiffness were named as $E0^{AE}$ and K_{r0}, respectively.

It is also known that steel plastic deformation generates AE signals with low amplitude, ranged from 30-35 dB, while in this study the fixed threshold level of 45 dB was assigned to data processing. Therefore, AE energy attained in the present work addresses the released strain energy in concrete specimens. However, a fairly well correlation can be found in Figure 7 till 50% of loading (Stage A) between E^{AE}/E_0^{AE} and K_r/K_{r0} which is displayed in top left side of Figure 7. Therefore, the following correlation can be made for the stage A:

$$E^{AE}/E_0^{AE} = K_r/K_{r0} = E_A^{AE}/E_0^{AE} = K_{rA}/K_{r0} = 1$$

On the other hand in stage B that can be found the following relation may correlate:

$$E^{AE}/E_0^{AE} = (\alpha)\ K_r/K_{r0} \text{ where in the end of test } \alpha \simeq 3$$

However, the loss of stiffness is a significant indication of damage degree imposed to a structure. Therefore, loss of stiffness can be taken into account as a damage severity indicator index. As a result, a damage index might be defined as following:

$DI = K_r/K_{ru}$

where in the ultimate level of damage, loss of stiffness reaches it maximum value at $Kr \rightarrow K_{ru}$, DI = 1. Considering the correlation between loss of stiffness and AE energy, damage index can be postulated as following:

$DI = (\beta)\ E^{AE}/E_u^{AE}$

where $\beta = 1/\alpha$, and E_u^{AE} is the ultimate value of E^{AE} in the end of the test. It can be observed that damage index showed an admissible relation with AE energy released during the fracture in composite ferrocement slabs and it could be a proper candidate for assessing the level of damage in concrete structures.

Intensity Analysis (IA)

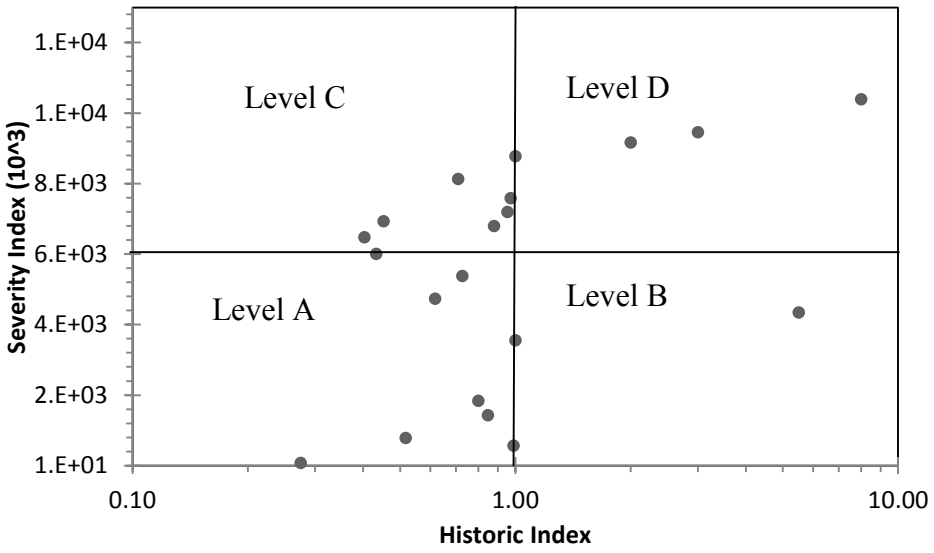
Intensity analysis evaluates the structural significance of an AE event as well as the level of deterioration of a structure by calculating two values called the historic index (HI) and severity (Sr) (Bagherifaez et al., 2014). The HI compares the signal strength of the most recent emissions to the signal strength of all emissions. This requires estimating the slope changes of the cumulative signal strength plotted as a function of time. The presence of one or more peaks may reveal the occurrence of new damage or the propagation of damage, respectively. As the severity is a measure of structural damage, an increase in severity often corresponds to new structural damage. Analytically, the HI and the Sr are defined as

$$HI = \frac{N}{N-K}\left(\frac{\sum_{i=k+1}^{N} S_{oi}}{\sum_{i=1}^{N} S_{oi}}\right) \quad (1)$$

$$S_r = \frac{1}{J}\left(\sum_{m=1}^{J} S_{om}\right) \quad (2)$$

Where N is number of AE emissions (referred to as 'hits') up to time t; S_{oi} is the signal strength of the *i*th event; *K* and *J* are empirical constants based on the material under investigation (Behnia et al., 2014b). Figures 8a and 8b present intensity chart and historic index profile for composite slabs, respectively. Results for all composite slabs affirmatively showed that state of damage can be quantitatively presented by intensity chart with some modifications applied in previous studies.

a)



b)

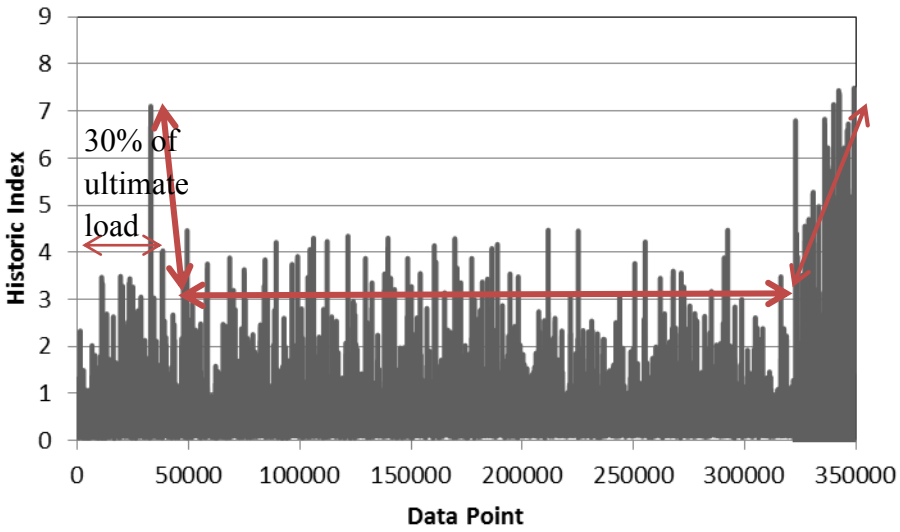


Figure 8 Intensity analysis for composite slabs: a) Severity versus Historic index, b) Historic index profile

The damage states in Figure 8a are categorized in four classes according to the relation between AE signal strength and loading percentile. Level A represents the stage prior to macro-crack occurrence from 0 to 30% of loading (low damage). Level B indicates the stage after macro-crack occurrence from 30% to 50% of loading strength (low intermediate damage). Level C implies higher level intermediate damage from 50% to 80% of ultimate strength (high intermediate damage). Level D belongs to severe damage relating final stage of loading strength of composite slabs prior to punching failure. It should be noted that historic index graph has been highlighted with two knees which are indication of two imperative changes in the composite slabs damage state. The first knee happened in the macro-crack occurrence stage (30% of ultimate loading) and the second one occurred prior to punching failure of composite slabs which are highlighted in Figure 8b. This can related to the large amount of energy released from high energy events resulting significant rise in the slope of the historic index.

On the other hand, the graph presented in Figure 8b shows a great potential to be used as a hazard rate function for reliability analysis. The historic index curve is used to develop hazard rate function and consequently a method of reliability analysis and evaluation of current condition of a structure. The three distinguishable stages in historic index curve resembling bathtub curve stages. This curve has three distinct stages. The first stage presents a decreasing failure rate which is called the infantile or early-life failures, where the system is adopting to the new situation. The second stage exhibits a constant hazard function, whereas the third stage is displaying a rising failure rate which is called wear-out stage. It is noted that the hazard function can be explained by a Weibull function as follows.

$$f(t) = \frac{\beta}{\eta}\left(\frac{t-\lambda^{\beta-1}}{\lambda}\right)\left(e^{-(t-\frac{\lambda}{\eta})^{\beta}}\right) \quad 3$$

where β is the shape parameter; $\boldsymbol{\eta}$ the scale parameter; $\boldsymbol{\lambda}$ the location parameter. The shape parameter, β, also known as the Weibull slope parameter from which the slope of the Weibull probability density function (pdf) can be obtained and the three stages of the bathtub curve is discriminated.

In Figure 9 the three stages are defined as bellow:

$\beta < 1$ infantile failure
$\beta = 1$ constant failure
$\beta > 1$ wear-out failure

However, the hazard function can be obtained from Equation 3 as follows.

$$f(t) = \frac{\beta}{\eta}\left(\frac{t-\lambda^{\beta-1}}{\lambda}\right) \quad 4$$

In order to plot the bathtub curve and hazard rate function of composite slabs failure, historic index was used as a frequency or failure rate to obtain Weibull parameters pertinent to each stage of failure. The results of Weibull analysis and failure function plot is presented in Figure 9.

It can be realized that in the first stage, infant mortality, the composite slab damage severity was high because of first breakage of slabs at the time of first macro crack emergence. In the infant mortality stage, the initial failure rate is high which can be an indication of sudden release of energy at time of macro-cracks occurrence for a short period. In the second stage, steady state, the rate of failure in slabs was constant at a very low failure rate. It can be inferred that, after macro-cracks occurrence, wire meshes in tension parts started to carry tensile load resulting in propagating cracks. The third stage, wear out, is the sudden increase of damage in composite slabs and local damages combined to form material or component damage with a very high rate as punching failure is a sudden failure. In the third stage the failure rate happening in a very short time due to the inherent characterises of punching failure.

In general, the failure can be considered as a local phenomenon rather than failure of a structural element. Local damages are occurring inside the composite slabs when signal strengths are increasing which finally resulted in composite slabs failure.

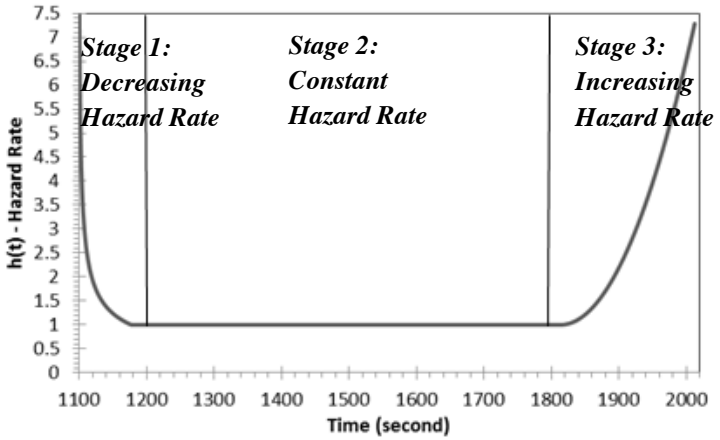

Figure 9 Bathtub curve for hazard rate function

CONCLUSIONS

In the present study, six samples of two types of multi-layer composite slabs with four and six layer meshes were prepared and examined until the final failure load. The slabs were tested under concentrated loads resulting in two types of failure, flexural and punching. Six R6I AE sensors were mounted on the slabs to monitor the failure of composite slabs during the loading process. Acoustic emission parameters such as AE energy and signal strength were investigated to find out the appropriate damage indication parameters. AE energy time history was used as input data for an auto regressive model of order 3 to present damage-sensitive features. Obtained damage sensitive features were used to plot different control charts to find out the relation between the variation of number of outliers and damage state in the composite slabs. In addition, using AE signal strength the highlighted damage in each stage was quantified. The following main conclusions were drawn from the results.

1. AE events with high energy contributed in fracture process zone, therefore, AE signal energy could be used as a proper damage index parameter to present the loss of stiffness in composite slabs.
2. AE signal strength showed a great potential to classify the level of damage in composite slabs and to be used for failure reliability analysis.
3. The proposed bathtub curve utilizing historic index divided the composite slabs failure in three distinctive stages which could enable one to predict punching failure as an abrupt failure.

Timber Structures

PRELIMINARY PERFORMANCE-BASED DESIGN OF A POST-TENSIONED GLUE-LAMINATED TIMBER FRAME

ABSTRACT

Post-tensioned timber joints have been studied at the Institute of Structural Engineering at the ETH Zurich. A post-tensioned beam-column timber joint has been developed using glued laminated timber with local hardwood reinforcement. Only a single straight tendon is placed in the middle of the beam and post-tensioned to restrain the rotation of the joint. No additional steel elements are used. The developed joint is characterised by a high degree of pre-fabrication and easy assembly on site. The glue-laminated timber moment-resisting frame featuring this joint shows great potential for timber frame structures especially for multi-storey buildings.
Robust performance-based design criteria are a necessity for a successful market implementation of the proposed system. A simplified analytical model was developed in order to predict the structural performance of the post-tensioned timber connection and facilitate preliminary performance-based design. This model was implemented in OpenSees using a bi-linear rotational spring approach. The model was verified against an analytical model and validated against tests on a post-tensioned timber joints under gravity loading and under horizontal loading. Moreover, a complex numerical model was developed using OpenSees to check the accuracy of the proposed preliminary design model.
The preliminary design model was used to design fictitious moment-resisting post-tensioned glue-laminated timber frame structures using the loads prescribed in the Swiss code. The design process showed that neither the gravity loads nor the seismic load controlled the design. The design was governed by the lateral deformations due to wind. Based on this finding it is recommended to focus further research on increasing the connection stiffness or on adding additional structural elements to address the seismic performance of post-tensioned timber frames in regions of high seismicity.

Post-tensioned, timber frame, performance-based design.

INTRODUCTION

In order to compete with structures made of concrete, timber structures have to be safe, economical, assembled quickly, and flexible. Timber frame structures fulfil the mentioned requirements. A disadvantage is the complicated connection between beam and column that are often bolted and reinforced with screws. These connections are able to resist a moment, which is however often neglected (Lam et al. 2010) and the beams are often designed as simply supported (Kolb 2008). A system that has been developed in New Zealand at the University of Canterbury is suitable for timber frames. The system uses the post-tensioning technique to provide for moment resistance and quick assembly (Buchanan et al. 2008, Newcombe 2011, Smith et al. 2011, Sarti et al. 2012, van Beerschoten 2013, Moroder et al. 2014). The system developed in New Zealand has been adapted at ETH Zurich to fit the European market. The result is a post-tensioned timber connection shown in Figure 1.

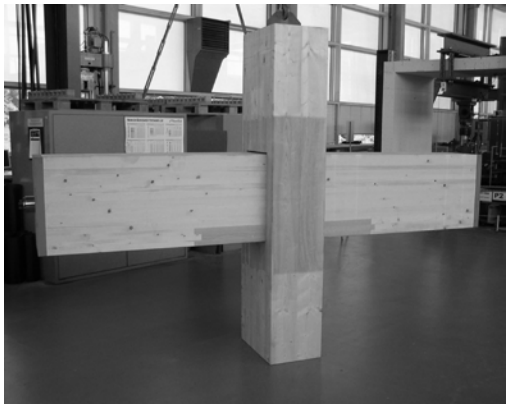

Figure 1 Post-tensioned timber connection with hardwood reinforcement (the darker areas are made with European ash)

The beam-column timber joint is made of glued laminated timber (Norway spruce, *picea abies*) with local strengthening of the column in the connection region using hardwood (European ash, *fraxinus excelsior*). No steel elements are required. Only a single straight tendon is placed horizontally through a cavity in the middle of the beams and the column to form the moment-resisting timber joint. The post-tensioned beam-column timber joint is characterized by a high degree of pre-fabrication and easy assembly on site.

The proposed system was evaluated in a series of large-scaled tests, i.e. tests under vertical loading on a post-tensioned timber connection (Figure 2 left, Wanninger and Frangi 2014b) and pushover tests on a post-tensioned timber frame (Figure 2 right, Wanninger 2015).

Figure 2 Tests on a post-tensioned timber connection under vertical loading (left) and tests on a post-tensioned timber frame under horizontal loading (right)

The tests demonstrated the self-centering behaviour of the proposed system under gravity loads as well as under horizontal loads. Practically no damage was observed during the test under gravity loads even for loads much higher than the design loads. A premature failure in a finger-joint occurred during the pushover-tests. However, this failure had no influence on the load bearing capacity of the frame, and only resulted in a deterioration of its lateral stiffness (Wanninger 2015).

MODELLING

Different models were used to evaluate the structural behaviour of the post-tensioned timber structural frames. An analytical model, a numerical model, as well as a simplified numerical model using rotational springs were developed and validated against the results obtained in the tests.

Analytical Model

An analytical spring-based model was introduced by the author and is described in more detail in Wanninger and Frangi (2014a) as well as in Wanninger (2015). The model assumes that the softer column can be replaced with springs embedded in the stiffer column. The model allows for calculating the connection behaviour with simple equations that can be derived using equilibrium conditions.

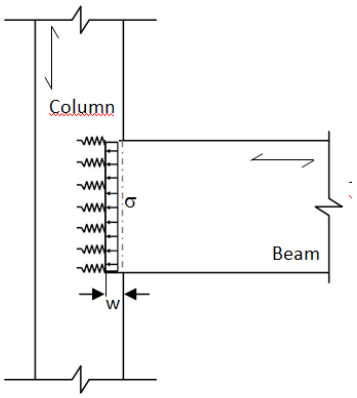

Figure 3 The analytical spring-based model with embedment analogy

Numerical Model

A model, based on the analytical approach described above, was developed using the OpenSees finite element modelling framework (McKenna and Fenves 2006) to simulate the behaviour of the connection specimen, which was subjected to vertical loading as shown in Figure 4. This model was subsequently used to simulate the pushover tests on the post-tensioned timber frame shown in Figure 5. Both models were created using these elements:

- Quadrilateral shell elements for the timber parts and also the steel plates (anchorage for the tendon)
- Corotational truss elements for the tendon (1D element)
- Zero length elements for the connection area to model the gap between the column and the beams

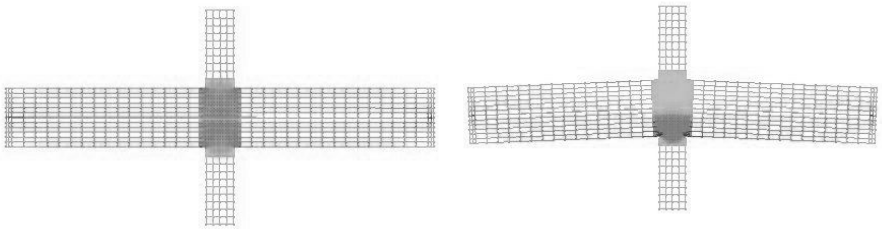

Figure 4 Numerical model of the post-tensioned timber connection subjected to vertical loading

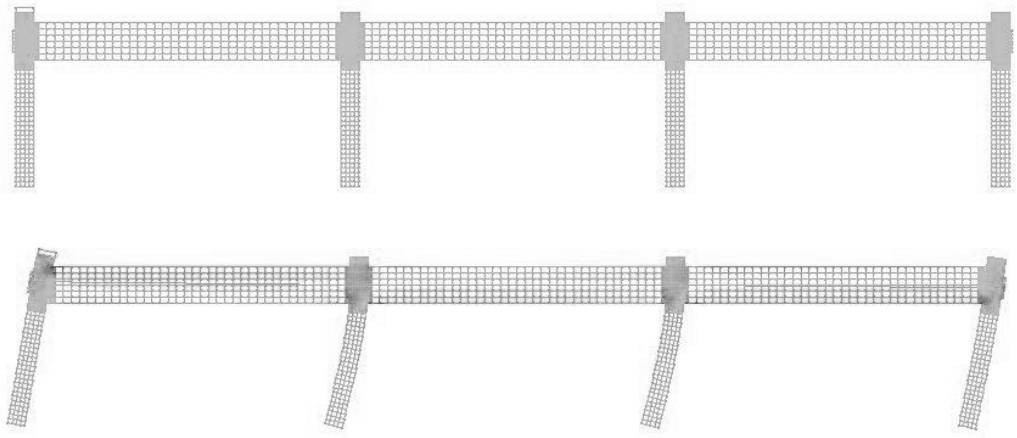

Figure 5 Numerical model of the post-tensioned timber frame subjected to horizontal loading

The material properties assigned to the model are identical to the properties used in the analytical model:

- J2-plasticity for the joint area of the model, which takes into account embedment failure perpendicular to the grain in the column (controlling design criterion)
- Elastic orthotropic material for the columns of the model, which takes shear deformations into account (pushover tests). The Poisson's ratio ν_{RL} was set to 0.059 (Green et al. 1999).

- Elastic isotropic material for the beams
- Uniaxial initial strain material for the tendon in combination with uniaxial material “Steel02”. The initial strain is used to apply the tendon force
- Elastic isotropic material for the steel plates at the end of the beams (anchorage)

Model Comparison

The obtained results from the analytical model (labelled “model”) as well as for the numerical model (labelled “opensees”) are shown in Figure 6 for the connection tests under gravity load and in Figure 7 for the frame pushover tests together with the experimental results.

Both modelling approaches match the test results under gravity load well (Figure 6). The numerical model also includes yielding of the tendon, which the analytical model does not.

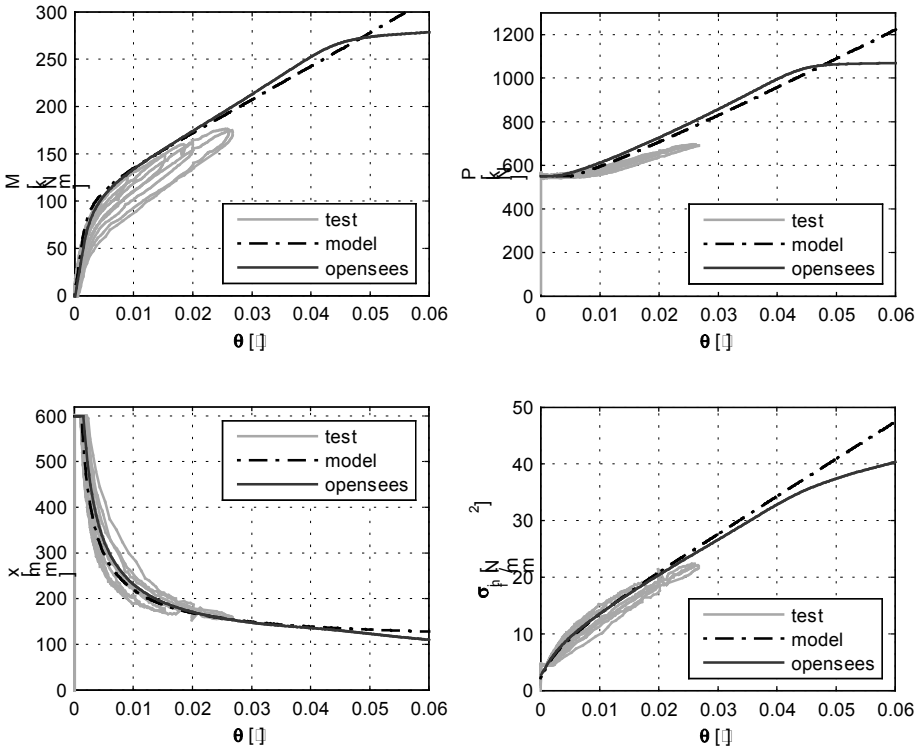

Figure 6 Results obtained from tests on the post-tensioned timber connection as well as analytical model (model) and numerical model (opensees). Shown are the Moment M, tendon force P, position of the neutral axis x, the stresses at the interface σ_{inf} over the connection rotation θ.

The results for the pushover-tests (Figure 7) were predicted well with the analytical model whereas the numerical model predicts a softer behaviour than actually measured during the tests on the frame specimen. The difference is a result of the simplifications made with the analytical model; the analytical model assumes rigid beams, whereas the numerical model takes their stiffness into account.

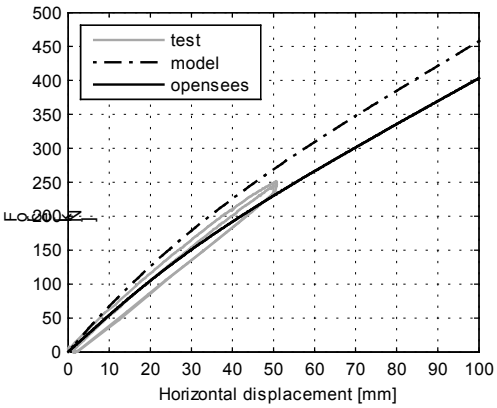

Figure 7 Results from the pushover tests with the analytical prediction (model) as well as the numerical prediction (opensees). The horizontal force F is plotted with the measured horizontal displacement of the frame

PRELIMINARY DESIGN

A preliminary design, presented in this section, can be performed using OpenSees or any similar software that is able to model a frame structure. The connection between the columns and beams is modelled using a rotational spring. The spring properties can be derived using either with the analytical or the numerical model presented in the previous section. The design is demonstrated on the ETH House of Natural Resources (Leyder et al. 2015), a building with a two-storey post-tensioned timber frame situated on the ETH Hönggerberg campus. The design is performed according to the Swiss SIA standards (SIA260, SIA261, SIA265).

Structure

The structural system of the building consists of a post-tensioned timber frame and two different slab systems. The frame has a height of 6 m (2 3 m stories and three 6.5 m span bays in both directions (Figure 8). The beams have a cross section of 720 × 280 mm and are made of glulam GL24h (SIA 265 2003). The hardwood columns have a cross section of 380 × 380 mm and are of the strength grade D40 (EN 338 2010). A tendon force of 500 kN was chosen to achieve the building design objectives. This force has to be guaranteed over the lifetime of a building: thus, the initial tendon force was set to 700 kN, i.e. nearly 30 % tendon force losses are accounted for (Wanninger et al. 2014c).

The slabs on the first storey are timber-concrete composite slabs, made using beech LVL (laminated veneer lumber) as reinforcement (Boccadoro and Frangi 2013). The slabs on the roof are also timer-concrete composite slabs made with beech LVL. The design of the slabs is more conventional; a 70 mm concrete slab is placed on beech LVL beams with a cross section of 240 × 80 mm. Under the beams are the 40 mm thick LVL plates acting as tension reinforcement (Figure 8). The design of the slabs will not be discussed herein. The span of the slabs was altered within each field of the frame to guarantee a uniform load distribution from the slabs to the frame.

The columns are modelled with pinned connections at the bottom to simplify the boundary conditions. The actual column support conditions are semi-rigid in order to facilitate the transfer of both gravity and horizontal loads.

Figure 8 Post-tensioned timber frame (left) and slab systems (right)

The gravity loads are summarised in Table 1. The weight of the frame itself is not listed in the gravity loads but it is taken into account in the calculations. The dead load of the 1st storey includes the weight of the slabs as well as the weight of the underlay and the floor covering. In addition to the dead load, 0.5 kN/m^2 were added to cover non-structural elements such as office partition walls. The dead load of the 2nd storey includes the weight of the slabs as well as the weight of the entire roof structure. The live loads are given by the standards for an office building (1st storey) and for a non-accessible roof (2nd storey). The snow load was calculated for the building's location in Zurich. The horizontal loads are also summarised in Table 1. The global wind force was calculated for the given building's geometry and its location. The ground acceleration is chosen according to the 2003 Swiss standards for a site in Zurich. The soil at the site is classified into seismic class C.

Table 1: Characteristic loads for the design of the post-tensioned timber frame based on the Swiss standards SIA

Gravity loads		1st story	2nd story
Dead load slabs	g_k	6.4 kN/m^2	4.7 kN/m^2
Live load	q_k	3.0 kN/m^2	0.4 kN/m^2
Snow loads	$q_{k,s}$	-	1.3 kN/m^2
Horizontal loads			
Wind force	$q_{k,w}$	1.0 kN/m^2	
Ground acceleration	$a_{g,d}$	0.6 m/s^2	

Design for Gravity Loads

The analysis was performed using OpenSees. The frame was modelled with elastic "BeamColumn-elements" as shown in Figure 9 (left) whereas the connection between beams and columns was modelled using rotational springs. The spring characteristic is shown in Figure 9 (right) and was derived with the analytical model described above. The spring used in OpenSees model is a trilinear-spring, therefore only approximating the moment-rotation behaviour obtained from the analytical model as can be seen in Figure 9 (right).

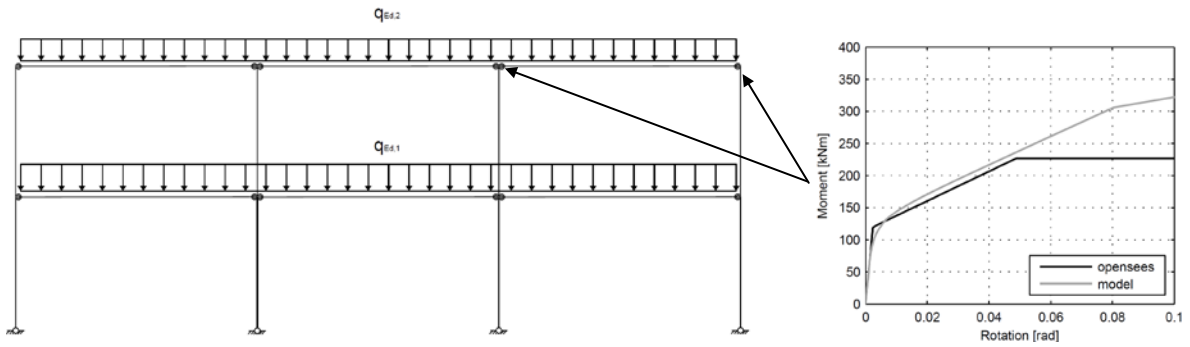

Figure 9: OpenSees model of the frame (left) and rotational spring characteristics for the beam to column connection (right)

The frame is loaded uniformly according to the characteristic loads given in Table 1. The loads for the design are calculated according to the Swiss standards for the first story:

$$q_{Ed,1} = (1.35 \cdot 6.4\ \text{kN/m}^2 + 1.5 \cdot 3.0\ \text{kN/m}^2) \cdot \frac{6.5}{2}\text{m} = 42.7\ \text{kN/m} \quad (1)$$

and the second story:

$$q_{Ed,1} = (1.35 \cdot 4.7\ \text{kN/m}^2 + 1.5 \cdot 1.3\ \text{kN/m}^2) \cdot \frac{6.5}{2}\text{m} = 27.0\ \text{kN/m} \quad (2)$$

The moments due to gravity loads are shown in Figure 10.

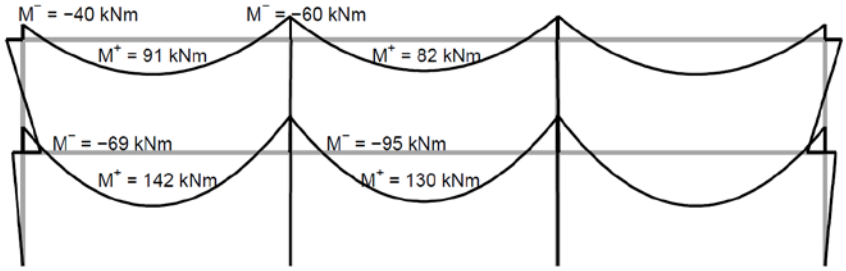

Figure 10: Design moments due to gravity loading

The design limit for the connection can be estimated with the analytical model described previously. The controlling design criterion is the compression strength perpendicular to the grain in the column, which is estimated at 8.6 MPa, including a factor for the load distribution. The design limits are summarised in Table 2 and compared to the values resulting from the gravity loads.

Table 2: Design under gravity loads and design limit according to Wanninger (2015)

Parameter		1st story	2nd story	Design limit
Load	q	42.7 kN/m	27.0 kN/m	62.0 kN/m
Stresses interface	σ_1	6.5 MPa	4.5 MPa	8.6 MPa
Moment interface	M	60 kNm	95 kNm	110.1 kNm

Seismic Design

The design is performed using three uniform hazard spectra (Giardini et al. 2013) with a return periods of 73, 475 and 2475 years as well as the design spectra derived from the Swiss standards (SIA 261 2003) for a soil class C ("Deposits of naturally consolidated and uncemented gravel and sand and/or moraine with a thickness exceeding 30 m") and a structural damping value of 5% (Figure 11). The design spectrum coincides with the UHS spectra with a return period of 2475 years (i.e. the maximal credible earthquake) for spectral displacements larger than 0.015 m.

The pushover curve for the building is generated with the same OpenSees model that was used for the gravity loads. The spring characteristics had to be altered in order to account for the shear panel deformations (Wanninger 2015). The gravity loads were added to account for the P-Delta-effect. The pushover curve for the two-story frame was transformed to a pushover-curve for an equivalent SDOF-system (Chopra 2007) and is plotted in Figure 11.

Based on the data in Figure 11, the building should withstand the design earthquake without collapsing; damage however can occur according the performance based design principles (Priestley 2000). The design earthquake leads to a roof displacement of approximately 0.02 m for the equivalent SDOF-system. This value translates to a roof displacement of 0.025 m for the two storey frame (Wanninger 2015).

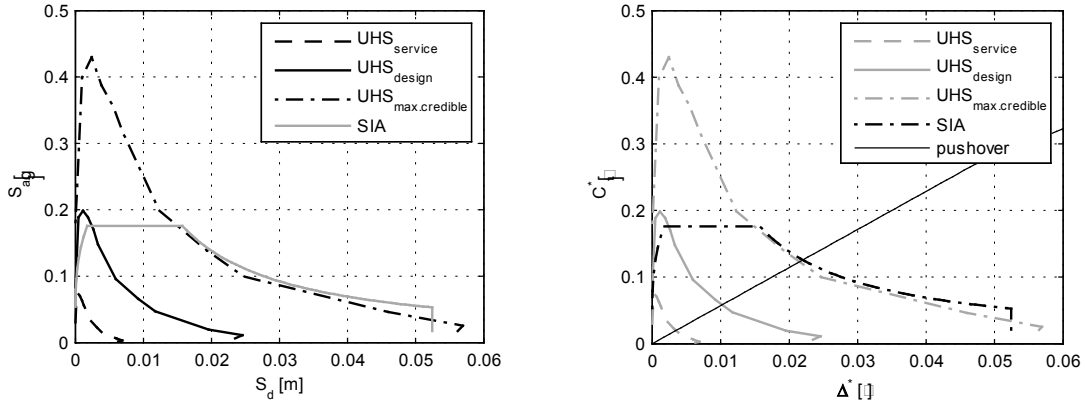

Figure 11 Capacity spectra for Zurich (left) and elastic design spectra with pushover curve for the two story timber frame (right)

The maximal moments resulting from the design earthquake are shown in Figure 12. The maximum connection moment is 58 kNm at the outer columns and 42 kNm at the inner columns.

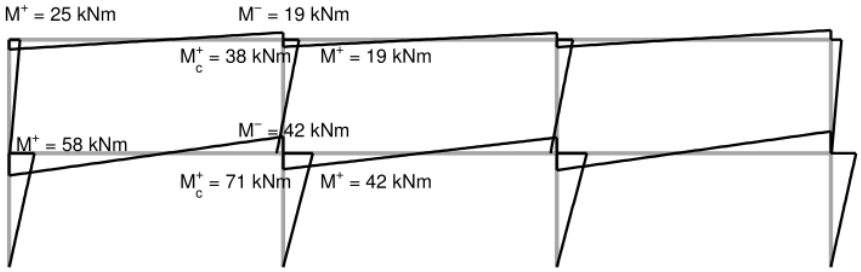

Figure 12 Moments due to the design earthquake (pushover-analysis)

The moments from the pushover-analysis (Figure 12) have to be added to the moments resulting from the gravity loads. The moments due to gravity loads acting on the structure during the design earthquake are plotted inFigure 13.

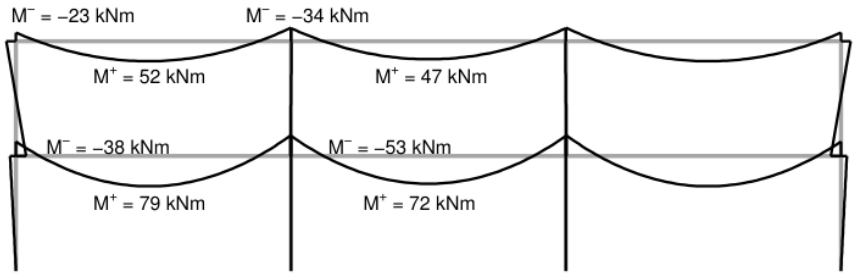

Figure 13 Moments due to reduced gravity loads

The maximum combined moment in a connection is 95 kNm (53 kNm due to gravity loads and 42 kNm due to the horizontal force). This moment is the same as for the design under gravity loads (see Figure 10). Therefore, the frame response remains in the elastic range for the design-level earthquake. Note that this earthquake is also the maximum credible earthquake as shown in Figure 11.

The frame would in theory be able to withstand larger earthquakes as the design earthquake In Zurich. To demonstrate this, the response of the frame to the East-West component of the Patti Gulf magnitude M=5.5 earthquake recorded at the station “Patti" on the 15th of April 1978 in Sicily. This earthquake is stronger than the design earthquake for Zurich and would lead to the moments that are plotted in Figure 14 (Wanninger 2015). The maximum connection moment of 124 kNm would lead to an exceedance in stresses perpendicular to the grain in the column without taking into account the 38 kNm from the gravity loads. However, the pushover tests that were performed on the post-tensioned timber frame specimen exceeded this moments without suffering much damage. The moments during these pushover tests exceeded 146 kNm (Wanninger 2015).

An unloaded frame (i.e. a frame carrying only horizontal loads) would therefore be able to withstand the Patti shock without any serious damage. If the gravity load has to be accounted for, the maximum moment would add up to 162 kNm, which exceeds the maximum moment obtained from the pushover tests by approximately 15%.

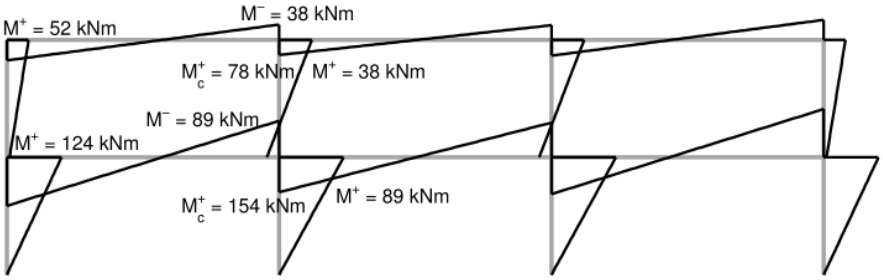

Figure 14 Moments due to the 1978 Patti earthquake

Wind Loads

The wind loads lead to smaller loads compared to the design earthquake. However, since the timber frame is a relatively soft system, the deformations under wind have to be checked.

The wind loads are applied to the structure as indicated in Figure 15, assuming that the façade is fixed at the top and the bottom of each story. It is assumed that the building has a height of 7 m including non-structural elements on the roof.

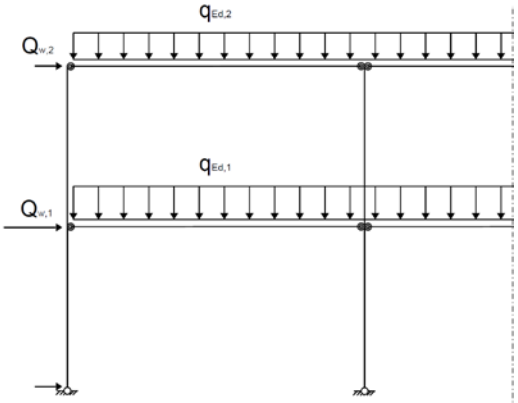

Figure 15 Model with wind loads

The loads for the top story are:

$$Q_{w,1} = 1.0\ \text{kN/m}^2 \cdot 6.5\ \text{m} \cdot \frac{3.5}{2}\ \text{m} = 11.4\ \text{kN} \tag{3}$$

and for the first story:

$$Q_{w,2} = 1.0\ \text{kN/m}^2 \cdot 6.5\ \text{m} \cdot 3.5\ \text{m} = 22.8\ \text{kN} \tag{4}$$

The wind forces in combination with the gravity loads load induce a roof displacement of 9 mm. This corresponds to a drift of H/666. However, the inter-story drift in the first story reaches a value of H/500 (i.e. 6 mm horizontal displacement). This corresponds to the limit given by the Swiss standard (SIA 260, 2003) for brittle installations and non-structural elements.

CONCLUSIONS

The design for gravity loads can be performed with a simple hand calculation or with the aid of software that is able to represent the non-linear moment-rotation behaviour of the post-tensioned timber connection using rotational springs.

The controlling design criterion is the stress in the column perpendicular to the grain. However, the tests under gravity loads lead to the conclusion that the joint can be loaded beyond the design value for the strength perpendicular to the grain without suffering from noticeable damage. Complying the requirements according to

the standards lead to large cross sections of the beams in order to distribute the load over a larger area and therefore reducing the stresses. This usually leads to beam sizes that would allow the beams to carry the applied gravity loads as simply supported beams.

The seismic design for areas with low seismic hazard, such as Switzerland, is not problematic. Displacement limits under wind loads control the design process, especially if brittle elements have to be accounted for leading to small allowable horizontal deformations of the frame. It is therefore recommended to install non-structural elements that are able to follow the frame in its deformations, i.e. that the deformation limits are less strict (H/300 instead of H/500). Moreover, it is advised to model the connection between the column and the foundation adequately so that its stiffness can be accounted for. Pinned connections are not suitable if the frame has to be designed for horizontal loads.

OUTLOOK

The pinned connections modelled at the bottom of the columns lead to a large horizontal displacement of the bottom story, which are controlling for the design (deformations under wind load). It is therefore necessary to estimate the actual stiffness of the connection at the bottom of the column. Tests on different kind of connections are planned and will deliver the needed data. Furthermore, the OpenSees model will be modified so that the same model can be used for horizontal and vertical load cases.

A COMPARATIVE LIFE CYCLE ASSESSMENT APPROACH OF TWO INNOVATIVE LONG SPAN TIMBER FLOORS WITH ITS REINFORCED CONCRETE EQUIVALENT IN AN AUSTRALIAN CONTEXT

Bella Basaglia [1,*], Kirsten Lewis [1], Rijun Shrestha[1], Keith Crews[1]
[1] University of Technology Sydney (UTS),
Faculty of Engineering and Information Technology (FEIT)
Building 11, 81 Broadway, Ultimo, NSW, Australia.*Email:bella.m.basaglia@student.uts.edu.au

ABSTRACT

The building sector contributes 24% of the total greenhouse gas emissions in Australia. This is expected to rise by 110% by 2050. Consequently, there has been an increased demand for more sustainable building materials which can play a significant role in reducing carbon emissions. Engineered timber wall and floor panels are being seen as a viable alternative for multi-storey buildings for both strength and environmental purposes and are gaining popularity in Europe, North America and New Zealand. A number of previous Life Cycle Assessments (LCA) comparing timber and concrete mid-rise buildings have highlighted the environmental benefits of using timber, particularly during material production and on-site construction stages. Furthermore, the choice of end-of-life scenario had a significant effect on the LCA outcome. The objective of this paper is to compare the environmental impacts associated with alternative designs for a long span floor in a multi-storey building in Australia. The comparison, using an LCA approach, is based on a recently built long span Timber Concrete Composite (TCC) floor in a University building in Sydney. Three design options are considered: the original design of TCC, a Cross Laminated Timber (CLT) panel, and a traditional in-situ reinforced concrete (RC) slab. The CLT and RC designs were conceived with reference to the floor plans and structural loads obtained from issued-for-construction drawings. With this evaluation, recommendations for increasing the competitiveness of CLT and TCC within the Australian market are made.

Sustainable materials, Cross laminated timber, Timber concrete composite, Life-cycle assessment.

INTRODUCTION

The Australian population is expected to jump by 60% from 23.3 million to 37.6 million by 2050 (Joye 2013). Increased foreign investment and historically low interest rates will push residential construction spending by 20% to just under $90 billion by 2017-18 (ACIF 2014). Particularly for multi-level apartment developments, 14.5% growth is expected in 2015 followed by a 4.1% increase for 2016. Commercial construction is also growing by 1.3% in 2015 and 1.5% in 2016 (Willox & Le Compte 2015). All these figures indicate that construction of new infrastructure and buildings is on the rise, and so will our greenhouse gas emissions.

The building sector contributes nearly a quarter of the nation's greenhouse gas emissions. This means that engineers, architects, and developers have the opportunity to decrease this figure by designing and constructing more sustainable buildings. Past construction has heavily involved concrete and steel, both of which are highly energy intensive when combining the materials production, transport and construction stages. However, timber has the potential to avoid majority of fossil fuel consumption and CO_2 release related to these conventional materials. Naturally through the photosynthesis process, trees produce oxygen by absorbing carbon dioxide which is then stored inside the wood. It is only when the wood decomposes in a landfill or during burning that the carbon is released back into the atmosphere. Hence, if wood products are used in construction, the carbon stored can be taken out of the carbon cycle for at least the duration of the life of the structure.

In this context, there has been a number of life cycle analysis (LCA) case studies undertaken comparing the embodied energy and embodied carbon of engineered wood products to concrete and/or steel construction (Buchanan & Honey 1994; Dolan & Harte 2014; John et al. 2011; Nassen et al. 2012; Page 2006). A particular study was undertaken by Oliver et al. (2012) comparing wood and a substitute product (steel or concrete) wall

and floor assemblies. The common theme throughout these studies is that the timber alternative has less environmental impacts than their concrete and steel counterparts and a greater use of wood in construction would lead to decreased CO_2 emissions. Furthermore, several case studies showed that due to the volume, floors have the highest or second highest potential for savings in embodied energy and carbon (Aye et al. 2012; Buchanan & Honey 1994; Dolan & Harte 2014). However, it is important to note that many of these aforementioned case studies did not consider the use of laminated timber (glulam and cross laminated timber).

This paper will compare the environmental impacts associated with three designs for a long span floor within a mid-rise building. The research will be based on a case study timber concrete composite (TCC) floor constructed in 2014 within the Oval Room of the Dr Chau Chak Wing Building of the University of Technology, Sydney (UTS). Alternative designs will include an innovative cross laminated timber (CLT) option and a more conventional reinforced concrete (RC) option. An LCA approach will be undertaken where various stages from cradle-to-grave will be discussed and compared. This will then be used to determine whether the inclusion of wood products within floor design provides improved environmental performance over conventional construction methods within Australia.

BACKGROUND

Engineered Wood Products

Structural timber comes in a number of different forms depending on the use, durability and strength required. Structurally graded sawn timber is the most commonly used material for domestic construction and is manufactured from both softwood and hardwood species. Hardwoods being denser than softwoods are therefore usually stronger and used for more high strength applications such as bearers and joists. Softwoods are used in general framing including studs, rafters and noggins. Sawn timber is cut from logs in standard industry sizes and is seasoned through a kiln drying process which ensures minimal dimensional changes. The timber is then visually or machine graded to determine the strength class.

Timber density can be increased even further through the manufacturing of engineered wood products (EWPs). EWPs are manufactures from thin veneers or small timber pieces which are then bonded together using a structural adhesive. This process allows EWPs to have more consistent structural properties. Two common EWPs used for structural applications include glulam and CLT.

Glulam

Glued-laminated timber is an engineered wood product produced by bonding a number of graded, seasoned, mostly finger-jointed sawn timber laminated with a structural adhesive (Figure 1(a)). The laminates are bonded with the grains running parallel and are therefore used for one-way spanning products such as beams. As the product is made up of a number of laminates, any strength reducing characteristics such as knots are removed. This results in a product which has a higher strength grade than the individual laminate pieces. Glulam is manufactured in Australia and has its own grade called GL in AS 1720.1 (2010).

Cross laminated timber

Cross laminated timber (CLT) is a prefabricated EWP generally manufactured from seasoned softwood. It is a panel element that is made up of usually three or five layers of orthogonally stacked timber boards which are bonded together with structural adhesives, as shown in Figure 1(b). The process of cross-lamination allows for improved dimensional stability and prefabrication of large floor and wall slabs. Due to the orthogonal nature, CLT has relatively high strength and stiffness characteristics in both directions, allowing it to act in two-ways similar to a reinforced concrete slab.

CLT was first developed in Austria and Germany in the 1990's and has been gaining increasing popularity throughout Europe and North America. There are several established manufactures of CLT in Europe, a few in North America and one in New Zealand. This means that if CLT is designed for an Australian structure, the panels will have to be imported from an overseas supplier. Despite this, at the time of writing, Australia is home to the tallest CLT building in the world with Forté in Melbourne.

There is currently no Australian standard which covers CLT. For CLT design in Europe, the 'gamma method' as outlined in Annex B Eurocode 5 Part 1 is used. This method accounts for the semi rigid link between layers by introducing a stiffness reduction factor. In Canada, the CLT Handbook (FPInnovations 2010) has been produced which provides comprehensive details of manufacturing, design and serviceability.

Figure 1 (a) Cross section of a glulam beam (BS Holz 2015) (b) Cross laminated timber layout (c) Cross-section of a TCC floor (Clouston & Schreyer 2008)

Timber Innovations: Timber Concrete Composite Floor Systems

A timber concrete composite (TCC) floor system consists of a timber beam, typically manufactured from glulam or laminated veneer lumber (LVL), connected to a reinforced concrete layer via a number of shear connectors, as shown in Figure 1(c). This means that there is only a small amount of slip at the interface as opposed to no slip if it were to act in a full composite manner. The strength of both materials is effectively utilized with the timber joist acting in tension and the concrete resisting the compressive stresses.

Availability of Wood Versus Consumption: Is It Sustainable?

Globally, the demand for wood has doubled in the last 40 years and is currently 3.4 billion m^3/year (UN-FAO 2012). This is expected to increase by just over 50% to 5.2 billion m^3/year by 2050 (Lam 2001). The concern has been raised as to whether forest harvesting is, in fact, sustainable. In particular, with laminated timber products such as LVL, glulam and CLT, larger volumes of timber will need to be processed. Do we have enough wood available to meet the potential global consumption? Can we manage harvesting sustainably? Oliver et al. (2014) collated a number of sources to obtain the average forest growth across all ecoregions and estimated that the potential global growth of wood is 17 billion m^3/year. This indicates that the world is harvesting approximately 20% of the potential growth if managed with moderate intensity (Oliver et al. 2014). Furthermore, it was found that by substituting wooden I-beams and plywood for a steel beam and concrete slab floor structure, an additional 27% of wood would need to be harvested. This means that forests and harvest rates are sustainable for efficient wood products.

On a more national level, in 2012-13, Australia harvested 22.8 million m^3 of wood from the 123 million hectares of native forests (FIAC 2015). However, although this seems sustainable, it has been projected that over the next forty years, softwood availability will increase only marginally at a rate of 0.5% per year (Ferguson et al. 2002). This is in contrast to a consistent growth rate of approximately 5% per year from 1959 to 2003 (Davidson & Hanna 2004). Softwood is the major source of production of EWPs within Australia and therefore could potentially highlight an area of concern for the EWP industry. This could result in higher consumption of imported softwood products to meet increased demand.

Life Cycle Assessment Approach

An LCA is an assessment tool that is used to outline the environmental impacts over a products life cycle. There are five main stages that are evaluated while undertaking an LCA on a building or a part of a building: (1) raw material acquisition, (2) material production, (3) construction phase, (4) operation and maintenance and (5) demolition/end of life disposal. In a number of case studies comparing the LCA of a timber framed building to an alternative concrete or steel building, the operation and maintenance phase was found to be very similar for all construction materials (Aye et al. 2012; Guggemos & Horvath 2005; John et al. 2011). These sources, combined with the fact that only the floor structure will be assessed, heating and cooling requirements and maintenance has been assumed to be constant for all floor design options in this paper.

To conduct a complete LCA, an inventory of relevant inputs and outputs of a system needs to be compiled. This information is usually obtained from databases which store inventories of the environmental burdens related to the manufacturing of a product. However, to date, there have only been a few LCAs conducted on engineered

wood products throughout the world. In the United States, the Consortium for Research on Renewable Industrial Materials (CORRIM) was the first to produce a database for forest and wood products. In a bid to address this gap in Australia, Forest and Wood Products Australia (FWPA) has collaborated with CORRIM to produce a Life Cycle Inventory of Australian forest and wood products (Tucker et al. 2009). An LCA of the floor system is not within the scope of this paper, however, the environmental impacts will be quantified based on two common measures: embodied energy (EE) and global warming potential (GWP).

EE is defined as the cumulative amount of primary energy consumed and stored throughout the raw materials acquisition, transport to factory and material production stages. Essentially, this is a cradle-to-gate measurement. This is usually measured in megajoules/kilogram (MJ/kg). GWP is the embodied carbon measured in $kgCO_2/kg$ of material and is a measure of the contribution of a product to potential warming of the atmosphere. It is important to note that energy consumption figures alone do not necessarily provide a good indication of the environmental effects associated with this consumption. However, the calculation is important in highlighting areas where significant reductions in consumption can be achieved (Aye et al. 2012).

METHODOLOGY AND KEY ASSUMPTIONS

This paper evaluates and compares the embodied energy and embodied carbon using an LCA approach of a long span TCC floor used in a multi-storey environment with different material alternatives. A case study floor is identified with structural drawings and loading plans used to design an approximate equivalent floor that could potentially be used in the place of the original design. Non-structural items such as services and ceiling boards that were installed post construction were not considered in this analysis. The surrounding framing system and the main concrete building that the Oval Room sits within was also not considered. The assessment was based purely on the floor system.

After the alternative floors were designed, a bill of materials was calculated for all three options. This includes the mass of timber, concrete and reinforcement required for each option. These values have then been used to evaluate the environmental impact in terms of EE and GWP of each design scenario.

Floor Design Assumptions

To allow a simple assessment, the floor envelope consists of a rectangular portion of the original Oval Room floor outline, as shown in the highlighted area in Figure 2. The envelope has a total floor area of approx. $45m^2$ with dimensions of approx. 10m long by 4.5m wide. This section of the floor has been selected as it includes the longest spanning area of the floor.

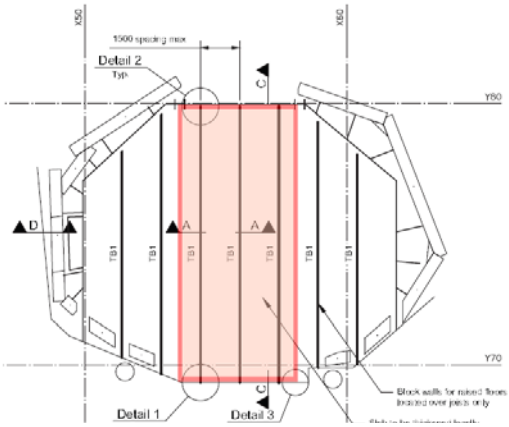

Figure 2 Plan of floor area to be assessed in this study (ARUP 2014)

The design of the alternative floors is based on the following general assumptions:

- simply supported floor system
- strength and serviceability limit states have been considered
- superimposed dead load of 1.5kPa and live load of 3kPa as per original design of the case study floor
- dynamics, acoustics and fire design have not been considered

Specific assumptions have also been made for each material used for the alternative options. The concrete will be of 40MPa strength grade with a 20 - 30% fly ash cement replacement mix. This is considered as a typical concrete mix for multi-storey buildings within Australia (Cement Australia 2015). The fly ash mix can be left

variable as it has been found that a simple change by adding 5% more fly ash has minimal effect on embodied energy of the concrete (Robertson, Lam & Cole 2012). The CLT panels are assumed to be supplied from KLH in Austria. KLH is the leading CLT manufacturer for the UK market (KLH UK 2015). KLH panels were also used for the Forté building in Melbourne. The 'gamma method' outlined in Eurocode 5 has been used.

System Boundaries

As mentioned earlier, conducting a whole LCA using Life Cycle Inventory data was not included in the scope of this assessment. EE and GWP rates have been researched from a variety of sources and the values from the most comparable reference have been used as a quantitative assessment of the floor structure from cradle-to-gate. Transport to the construction site is included in the construction stage. The operation and maintenance stage of the LCA has not been considered as it is assumed the energy required when the floor is in use will be similar for all materials. A qualitative investigation and review was then undertaken on the environmental implications of the on-site construction stage, transportation during construction and end-of-life choices.

THE CASE STUDY

Case Study Floor: Dr Chau Chak Wing Oval Room

The case study floor is located within the Oval Room of the Dr Chau Chak Wing Building completed in 2014. The building is part of the UTS and is located in Haymarket within Sydney's CBD. The Oval Room structure, engineered by ARUP, is 10.4 m high and consists of two 'log cabin' style classroom levels which are intricately framed by 142 glulam blocks stacked on top of each other.

The case study is based on the TCC floor on the first level of the Oval Room structure. The design consists of 450mm wide by 580mm deep glulam beams spaced at 1500mm connected to a 120mm reinforced concrete topping via notched birds-mouth shear connections. The floor has a clear span of 10 metres. The glulam was manufactured and imported from New Zealand. A plan and cross section of the floor is shown in Figure 2 and Figure 3, respectively. Reinforcement in the concrete was purely for shrinkage and crack control and consisted of N10 bars at 300mm spacing on the bottom running both ways and a SL102 mesh on top.

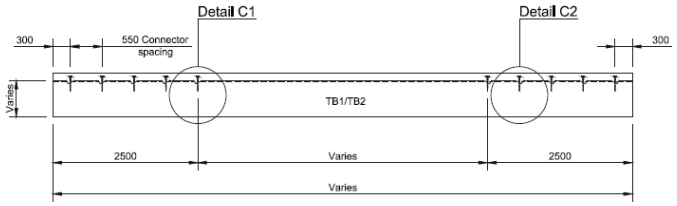

Figure 3 TCC floor cross section (ARUP 2014)

The CLT Panel Option

A 320mm thick CLT panel would be required for a 10m span which was governed by deflection. The panel would consist of five layers with 80mm lamella thickness for the top, middle and bottom layers and 40mm thickness for the second and fourth layers. As the panel would be spanning in one direction, the direction of the fibre of the odd numbered layers would be running parallel to the span.

The floor would be separated into three panels with equal dimensions of 1.5m wide x 10m long. When sizing CLT panels, both the supplier's standard dimensions as well as the shipping container dimensions need to be considered. KLH produces panels with a maximum length of 16.5m, maximum width of 2.95m and thickness of 0.5m. In regards to shipping, a High Cube standard container has internal dimensions of 12m in length, 2.65m in height and 2.33m in width. Therefore, the nominated panels would fit within one container when stacked.

The Reinforced Concrete Floor Option

The reinforced concrete (RC) floor alternative was originally designed to be a 440mm thick one-way spanning slab. Due to the 10 metre span, the design was governed by deflection limits and a large amount of reinforcement had to be used. This ensured the reinforcement to concrete ratio contributed enough to the effective second moment of area calculation in order to reduce deflections. This thickness would not be economical in practice.

Typically, for spans over 7m, prestressed concrete would be used as the net savings in material cost can range between 10 – 20% when compared to a reinforced concrete alternative (Roy 2008).

It is crucial that this study remains unbiased towards any particular material and represents design practice as best as possible while staying within the scope of the paper. Therefore, several alternative measures have been undertaken which increased reinforcement ratio in order to reduce the concrete depth. This has resulted in a 335mm thick slab with N32 bars at 100mm spacing for use in this study. This design satisfies AS 3600-2009.

RESULTS AND DISCUSSION

Material Quantities

A quantities take-off for the materials contained in the TCC, CLT and RC floor designs have been calculated in order to undertake a comparison of the EE and GWP. Approximate material quantities can be seen in Table 1. As the shear connections in the TCC design only contribute to less than 1% of the total material quantities, they have been considered negligible for the purposes of this study.

Table 1 Material quantities of different floor design scenarios

Material group	Unit of measurement	TCC design	RC design	CLT design
Concrete	kg	13762	38417	-
Steel (Reinforcement)	kg	190	2912	-
Timber (CLT)	kg	-	-	7339
Timber (Glulam)	kg	3759	-	-

Embodied Energy and Global Warming Potential

In order to quantify the EE and GWP of each floor structure, a number of references were sourced that had already conducted an LCA on different construction materials. For the purposes of this study, values from Alcorn (2003) have been selected to be used for multiplication with bill of quantities data. These values have been presented in Table 2. Although these values are for New Zealand building materials, the properties of the material most closely relate to the materials used within this case study. There are also a number of other studies that provide embodied energy and carbon data relevant to Australian context (Buchanan & Honey 1994; Fernandez Perez 2008; John et al. 2009; Treloar & Crawford 2010).

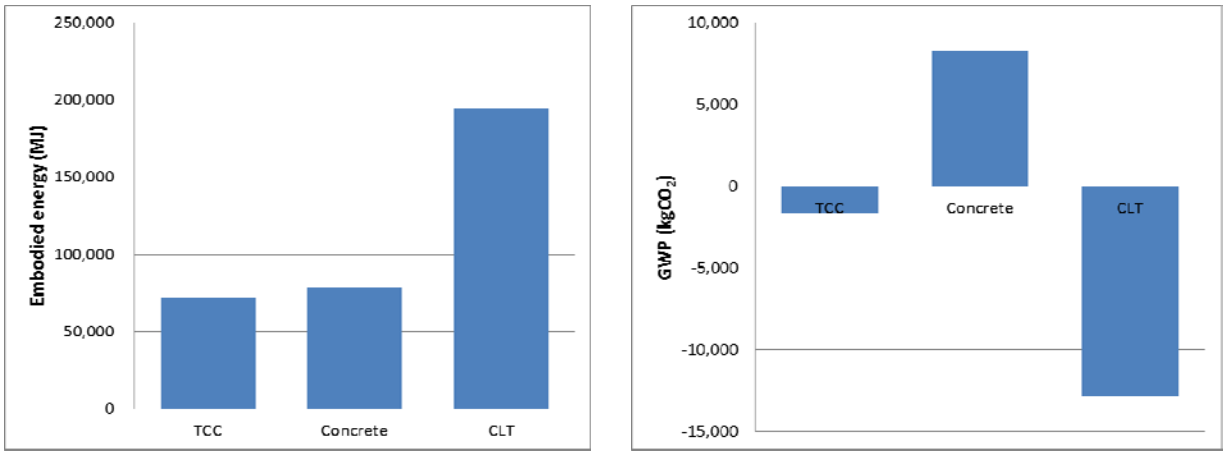
Table 2 Embodied energy and embodied carbon from different sources (Alcorn 2003)

Embodied energy (MJ/kg)			GWP ($kgCO_2/kg$)		
Glulam	Concrete	Steel Reinforcement	Glulam	Concrete	Steel Reinforcement
13.6	1.4	8.6	-1.141	0.189	0.352

There have been very few LCA's conducted on CLT building case studies, particularly due to the fact that it is a recent EWP. However with the recent completion of the Forté building in Melbourne, FWPA have published a LCA comparing the Forté building to a reinforced concrete equivalent (Durlinger, Crossin & Wong 2013). It concluded that the GWP of the building materials for the Forté building were 30% lower than the reference building, however, this did not include transportation to the building site. KLH have produced an environmental product declaration in accordance with ISO 14025:2006 (ISO 2006). Since embodied energy accounts for a cradle-to-gate system boundary, these figures will be used for evaluating the embodied energy of the CLT floor design option. The values have been presented in Table 3.

Table 3 Embodied energy and GWP values of CLT (KLH 2012)

	GWP ($kgCO_2/kg$)	Non-renewable primary energy (MJ/kg)	Renewable primary energy (MJ/kg)
CLT – 320mm thick panel	-1.75	3.11	23.44



(a) (b)

Figure 4 (a) Embodied energy and (b) GWP of three alternative floor structures

Figure 4(a) indicates that the concrete floor option is comparable to the TCC option in terms of embodied energy with only a 10% difference. The inclusion of concrete in the TCC floor system contributes approximately 20% of the total embodied energy. The CLT option is nearly 2.5 times more energy intensive than both the concrete and timber options. However, it is important to remember that 88% of this energy is derived from renewable sources. As expected, Figure 4(b) reveals that the concrete option has the largest GWP. The carbon stored in the glulam from the TCC option outweighs the carbon emitted from the concrete portion of the system and therefore there is still 1.6 tonnes of carbon that can be credited. The CLT option has the least amount of GWP with the floor system reclaiming nearly 8 times the carbon contained within the TCC system. This accounts to over 12 tonnes of recovered carbon.

On-site Construction and Transport

The construction stage of an LCA consists of the actual construction and erection of the building or structural system being investigated. Cole (1999) categorised the construction stage into five main areas: (1) transportation of crew to site, (2) transportation of materials to site, (3) transportation of plant and equipment to site, (4) use of on-site equipment and (5) any supporting processes such as formwork. Generally, it has been found that the transportation of workers to and from site is the largest contributor to construction energy and greenhouse gas emissions (Cole 1999).

Construction methods for the three different scenarios would be as follows:

- Wet concrete: typically delivered to the building site from a central batching plant using a diesel powered mixer truck in order to keep the concrete fluid during transport. The transport distance is governed by the setting time of the mixed concrete.
- Glulam: flat deck trucks would generally be used to transport the glulam from the supplier to site. In the case that the glulam is imported (this case study), the elements would be shipped from the supplier.
- CLT: panels would be imported from Europe and involves shipping as well as trucking from port to site.

A study undertaken by Cole (1999) concluded that cast-in-place concrete assemblies have the highest construction energy and greenhouse gas emissions per square metre ranging from 90 – 120 MJ/m2 and 13 – 20kg/m2, respectively. Transportation of workers was the largest contributor at approximately 40 – 50% of the total. This is most likely due to the additional trades introduced with wet concrete including formwork and propping. In fact, Guggemos (2005) noted that minimising the amount of temporary materials used, including reusing temporary materials where possible, is one of the main areas that could assist in reducing impacts. Cole (1999) also obtained results for the construction of glulam frames (for spans of 6.1 – 9.2m) and found that energy use and carbon emissions were 17 – 20MJ/m2 and 2.3 – 2.5 kg CO2 eq./m2, respectively. These values reveal that concrete construction is significantly more energy intensive than timber.

Junnila (2006) undertook an LCA case study on a mid-rise commercial building in Europe and the US, both having RC slabs. In contrast to Cole (1999), it was found that equipment use accounts for the majority of energy use and emissions during the construction stage. Findings from Guggemos and Horvath (2006) also show that emissions during the construction phase were mainly as a result of the frequent use of heavy diesel equipment.

It is also important to note that construction times associated with timber buildings, in particular using CLT panels or prefabricated sections, are significantly less when compared to in-situ concrete. For example, a study undertaken on the Stadthaus, a 9 storey apartment building in London with 8 storeys of CLT floors, had found that there was a 22 week saving in program time by choosing CLT over concrete (Toosi 2011).

Despite these results, it has been concluded from a number of researchers that the construction phase has relatively small impacts to the overall life cycle. Gong et al (2012) case study on multi-storey residential buildings in Beijing revealed that contribution from construction is less than 2% of the total life cycle. Furthermore, Guggemos and Horvath's (2005) two case studies on commercial buildings in the US have found that contribution from construction is 0.4 – 11%.

Based on the above literature review, it can be estimated that the RC floor option would be the most energy intensive due to the equipment use. However, the CLT floor option may be comparable or potentially more energy intensive when considering the shipping of the panels from Austria where an LCA undertaken on the Forté building estimated that GWP for transport of CLT was 8.2 times that of a concrete option (Durlinger, Crossin & Wong 2013). The energy consumption and GWP of the TCC floor is estimated to be between the concrete and CLT options due to the combination of both wet trades and timber.

Demolition and End of Life Scenarios

There are two definitions of the end of life phase of an LCA. One definition involves all activities related to the demolition of the building, waste of materials, transport of materials off-site and the consequent recycle, reuse or landfilling of materials. Another definition supported by Guggemos and Horvath (2005) and Aye et al. (2012) argues that the potential future use or disuse of demolished materials is uncertain and cannot be guaranteed when the process occurs in over 50 years' time. However, their argument states that if the materials are recycled, this should be credited for within the materials production stage of the LCA of the new building in which these materials are used.

There has been unanimity among researchers that the demolition portion of the end of life phase is insignificant in relation to the overall life cycle energy use and carbon emission of a building (Crowther 1999; Gustavsson, Joelsson & Sathre 2010). Many studies (Aye et al. 2012; Cole & Kernan 1996; Junnila, Horvath & Guggemos 2006) have even disregarded this section altogether within their LCA.

Currently in New South Wales, approximately 95% of concrete is recycled (Hyder Consulting 2011). This rate is similar in other capital cities. Timber, however, has a limited reuse capacity and is mostly taken to landfill. When timber decomposes, carbon is released; although, the rate of decomposition is slow. Research by Ximenes et al. (2006) have revealed that more than 95% of the carbon in wood remains stored even after 30 years in landfill. Regardless of this, eventually the stored carbon and methane which has 25 times more warming potential of CO_2 will be emitted and has the potential to contribute up to 85 per cent of Australia's carbon budget in 2050, depending on the reduction target (Angel & Castle 2007).

This highlights the potential and benefit of incinerating timber waste with energy recovery. A study undertaken by Robertson et al. (2012) has revealed that timber design has over five times more feedstock energy than a concrete design scenario. Feedstock energy is the easily accessible potential energy contained in renewable fuel sources that can be used to form another fuel or energy product. The high amount of feedstock energy in both glulam and CLT indicates that the materials can be readily combusted and utilised as energy sources after their useful life (Robertson, Lam & Cole 2012). The use of this recovered bio-energy instead of fossil fuels has the potential to significantly reduce the net emission of CO_2 (Gustavsson, Joelsson & Sathre 2010). If the end result of the material in the end of life phase is included, the recovered energy can be subtracted from the total energy use of the building.

In a study undertaken by John et al. (2009) both landfill and reutilisation scenarios were investigated for four different building frames. The landfill scenario assumed all building materials would be sent to landfill while in the reutilisation scenario wood waste was used for energy and all concrete and steel was recycled. It was found that in the reutilisation option, total primary energy use was lower than in the landfilling scenario for all four buildings. When comparing the total GWP of the concrete and timber buildings in the reutilisation phase, the concrete building had 13% greater GWP. This is due to the fact that over 25 times more CO_2 was retained from the reutilisation of wood waste from the timber building than the concrete building which was credited into the total GWP.

Considering the above references, the demolition stage of the floor system in this study, regardless of material, can be assumed to be minimal when looking at cradle-to-grave energy consumption and carbon emissions. It is difficult to speculate future use and end of life scenarios in 50 years' time. However, it can be estimated that if wood waste from the TCC and CLT floor options was burned and feedstock energy was recovered, the total GWP involved in the whole life of the floor system would be less than the concrete option.

CONCLUSIONS

This paper has evaluated and compared the environmental impacts through an LCA approach of three different design options for long span floors, namely RC, TCC and CLT. In terms of embodied energy, results indicate that a TCC floor system is comparable to an RC floor system. The CLT floor option contained the most embodied energy but the least amount of GWP where nearly 12 tonnes of carbon could be recovered from a potential LCA. The RC floor option contained the largest amount of GWP which can be accountable to its energy intensive production process.

A qualitative assessment was undertaken on both the construction and end of life phases of the three floor design options. From review of various references, it was concluded that on-site construction does not significantly contribute to the total primary energy and GWP of a floor system. Due to the wet trade and supporting processes involved, the RC floor option would potentially have the highest primary energy and GWP out of all floor scenarios. During the end of life phase, a large opportunity in reducing total energy consumption and GWP becomes apparent if feedstock energy contained within timber products can be accessed. If this scenario were to be explored for the CLT and TCC floor options, energy and carbon could be recovered from a cradle-to-grave assessment.

Many comparative LCA case studies have not included the use of EWPs such as glulam and CLT. This paper has illustrated the environmental benefit of using timber products within a long span floor structure when compared to a typical RC construction process.

ABSTRACT

This paper compares the structural performance between thin-walled timber and FRP-timber composite Cee-sections. While, thin-walled composite timber structures have been proven to be efficient and ultra-light structural elements, their manufacturing is difficult and labour intensive. Significant effort and time is required to prevent the cracking of the transverse timber veneers, bent in the grain direction, when forming the cross-sectional shape. FRP-timber structures overcome this disadvantage by replacing the transverse veneers with flexible, unidirectional FRP material and only keeping the timber veneers which are bent in their natural rolling direction. The Cee-sections investigated in this study were 210 mm deep × 90 mm wide × 500 mm high and manufactured from five plies. For both section types, the three internal plies were thin (1 mm thick) softwood Hoop pine (*Araucaria cunninghamii*) veneers, orientated along the section longitudinal axis. The two outer layers, providing bending stiffness to the walls, were Hoop pine veneers (1 mm thick) for the timber sections and glass fibre reinforced plastic (0.73 mm thick) for the FRP-timber sections orientated perpendicular to the inner layers. The manufacturing process is briefly introduced in this paper. The profiles were fitted with strain gauges and tested in compression. Linear Variable Displacement Transducers also recorded the buckling along one flange. The test results are presented and discussed in this paper in regards to their structural behaviour and performance. Results showed that the use of FRP in the sections increases both the elastic local buckling load and section capacity, the latter being increased by about 24 percent. The results indicate that thin-walled FRP-timber can ultimately be used as a sustainable alternative to cold-formed steel profiles.

KEYWORDS

Ultra-light thin-walled structures, sustainable design, laminated timber structures, glass fibre reinforced plastic (GFRP).

INTRODUCTION

Increasing focus is being placed on sustainable design and construction materials resulting in many innovative approaches taken to reduce carbon emissions and increase the effectiveness of engineering structural products. One pathway is to improve the competitiveness of timber products when compared to their steel and concrete alternatives. In an attempt to create ultra-light structural elements, increase the use of timber in the construction industry and improve the profitability of the forest industry, thin-walled composite timber sections were proposed and investigated by Gilbert et al. (2014). The sections, in the form of Cee-sections with web and lip stiffeners, attempt to mimic cold-formed steel profiles through the use of a sustainably grown material. The research established that the proposed sections, when tested in compression, were able to compete with or exceed cold-formed steel products in terms of weight-to-capacity ratio.

It was noted in Gilbert et al. (2014) that delamination likely occurred within the studied specimens as a result of the experimental manufacturing techniques used. Also, the manufacturing required significant time and effort to prevent cracking of the transverse timber veneers (bent across the grain direction) when forming the cross-sectional shape. Nevertheless, damage to these veneers was still commonly observed in the studied sections. To overcome this disadvantage, this paper investigates the replacement of the transverse veneers with a flexible FRP material. Only the timber veneers which are bent in their natural rolling direction are kept, therefore creating ultra-light FRP-timber composite sections that can be manufactured faster, with less difficulty and an increase in transverse properties compared to the timber-sections.

This paper experimentally investigates the compressive performance of thin-walled timber and FRP-timber Cee-sections. An outline of the manufacturing process for both section types is given. Stub-column tests were performed and the sections were monitored throughout testing using a combination of strain gauges and transducers, enabling the structural performance and behaviour of the sections to be presented and discussed.

INVESTIGATED SECTIONS

General

Three thin-walled FRP-timber and two timber composite Cee-section specimens were manufactured in this study. The sections were manufactured in a 5-ply configuration with overall dimensions of 200 mm deep x 90 mm wide x 500 mm high, and an internal bending radius of 12 mm. The three internal timber layers for both section types were thin softwood Hoop pine (*Araucaria cunninghamii*) veneers, with a nominal thickness of 1 mm per veneer, and were layered with the grain direction orientated along the longitudinal axis of the section. For each specimen, the three internal veneers were cut from the same larger veneer sheet to maintain consistent material properties within each specimen. For the full timber sections, the external layers were cut from the same larger veneer sheet, albeit a different sheet to the internal layers, and orientated perpendicular to the inner layers. For the FRP-timber sections, the external layers (also orientated perpendicular to the inner layers) were unidirectional FRP, composed of glass fibres and polyurethane, with a combined thickness of 0.73 mm. Figure 1 outlines the specimen dimensions and grain orientation. Contrary to the sections studied in Gilbert et al. (2014), the present sections are simple Cee-sections, without web and lip stiffeners, for the purposes of manufacturing simplicity and better monitoring the compressive behaviour of the sections (see Section *Stub-column test setup*)**.** The Hoop pine veneers were glued together with resorcinol formaldehyde structural adhesive, while polyurethane was used to bond the GFRP to the timber. Polyurethane was chosen over an epoxy (those typically used in GFRP-to-concrete and GFRP-to-steel bonded joints) as it was found to provide a stronger bond to the timber.

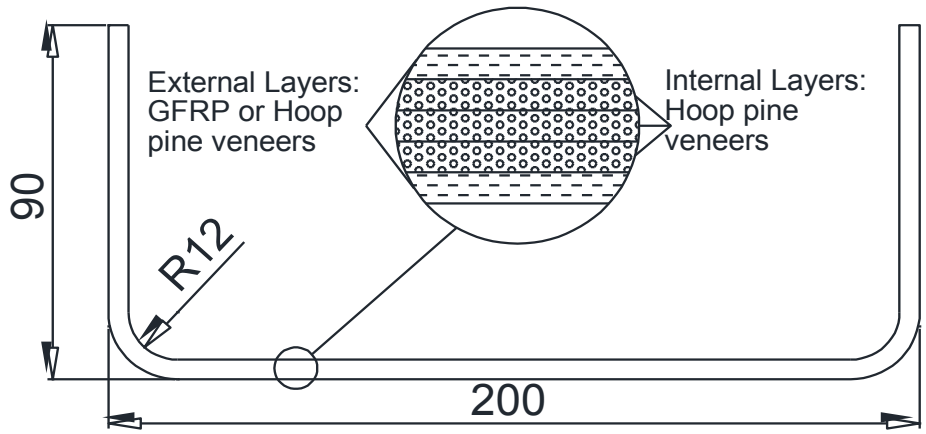

Figure 1 Dimensions and grain orientation of Cee-Sections

Manufacturing Method

Gilbert et. al. (2014) identified that delamination between the timber layers likely occurred as a result of low pressure application during the glue curing stage. In this study, the manufacturing jig was improved and the recommended glue manufacturer pressure was applied to the web while pressure on the flanges was increased through a series of heavy duty clamps. The pressure applied to the corner was also increased through the application of pressure from a thin aluminium sheet wrapped around the specimens and forced up on both sides. A schematic of the manufacturing jig used is shown in Figure 2 (a). The manufacturing process is outlined below with the steps being divided into common steps and specific steps for each section type.

Common steps

Step 1: 2.5 m x 1.2 m Hoop pine veneer sheets, 1 mm thick, were delivered and pieces were cut for specimen manufacturing and material property identification. Imperfections such as knots and cutting creases were avoided in the cut pieces.

Steps 2 to 4: Refer to the specific steps for each type of section below.

Step 5: Flanges and ends of specimen were trimmed to size.

Step 6: Specimens were placed in a climate chamber at constant temperature and relative humidity to reach equilibrium moisture content before testing as a stub column.

FRP-timber specific steps

Step 2: The three timber layers were glued around the jig (using resorcinol) and pressure was applied for 48 hours.

Step 3 The specimens were placed in a climate chamber at constant temperature and relative humidity and allowed to reach equilibrium. This ensured that the polyurethane had appropriate amounts of water within the timber to react with when applied to the specimen.

Step 4: The GFRP was then glued to the specimens around the jig (using polyurethane) with pressure being applied for 24 hours.

Note: Step 4 could be conducted at the time as step 2 in the future if the same glue is used for all surfaces.

Timber composite specific steps

Step 2: The external layers were soaked in water for 48 hours to enable their bending across the grain with minimum cracking in the timber.

Step 3: The soaked veneers were moulded into shape around the jig without the aluminium sheet, with the dry internal layers, through the use of a water steamer. This exposed the corners allowing them to dry faster. The jig was then placed in an oven at 40^{o}C for 30 minutes until the veneers could be released from the jig without losing their shape. After removal from the oven, the layers were removed from the jig, separated and held loosely in their desired shape through flange restraints in an air-conditioned room until gluing.

Step 4: All layers were glued together around the jig after they reached equilibrium moisture content. Pressure was applied for 48 hours.

A photo of the final manufactured full timber specimen, prior to trimming (Step 5) is shown in Figure 2 (b).

MATERIAL TESTING

The Modulus of Elasticity (MOE) and Modulus of Rupture (MOR) parallel and perpendicular to the grain, for all timber veneer sheets constituting the cross-sections were measured.

The MOE was measured using an acoustic non-destructive method (Brancheriau, 2002). Six strips of 300 mm long and 50 mm wide, representing three strips parallel to the grain and three perpendicular to the grain, were cut from each large veneer sheet. The strips were simply-supported on two rubber bands and impacted with a hammer. A microphone recorded the vibrations which were analysed using the Beam Identification by Non-destructive Grading (BING) software (CIRAD 2015). The results are given in Table 1.

To measure the compressive MOR, 20 rectangular pieces were cut from each large timber veneer sheet and glued together to manufacture 100 mm long and 50 mm wide samples. Three samples representative of the parallel grain direction and two samples representative of the perpendicular grain direction were manufactured per veneer sheet. The samples were tested in compression till failure using a 500 kN capacity MTS universal testing machine at a stroke rate of 0.16 mm/min to achieve failure in 1-5 minutes in accordance with AS/NZS4357.2:2006. This rate also represented the same strain rate at which the Cee-sections were tested. All samples were conditioned at the same constant humidity and temperature as the timber and FRP-timber sections to reach an average oven dry moisture content of 13.9%, determined according to AS/NZS2098.1:2006. The MOR perpendicular to the grain direction was determined using a 1% strain offset as outlined in EN 408:2003. The results are summarised in Table 1.

The mechanical properties of the GFRP were also measured but are not shown in this paper.

Table 1 Mechanical properties of timber veneers used

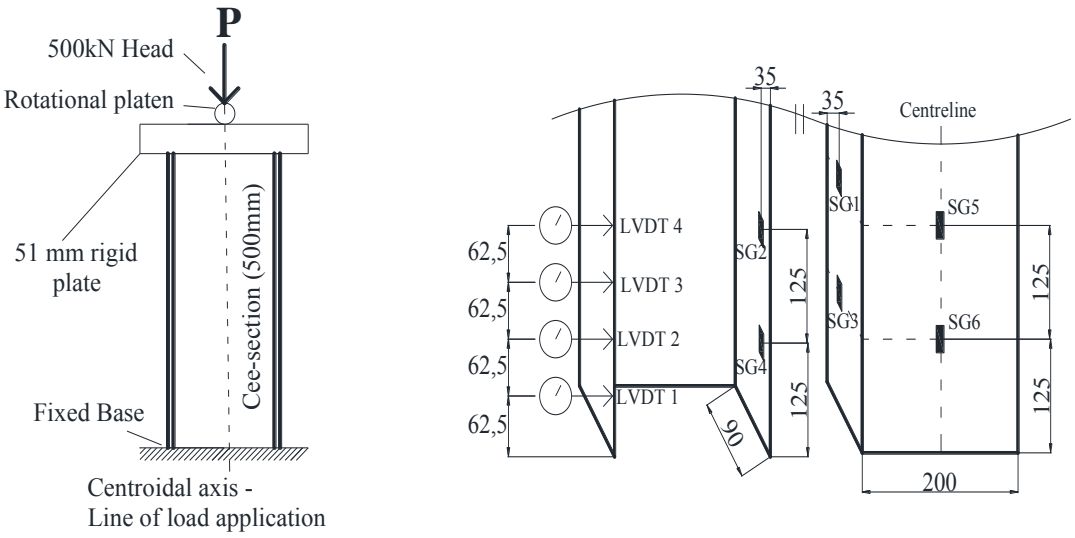
STUB-COLUMN TEST SETUP

The nominally 500 mm high specimens were tested in compression using a 500 kN MTS universal testing machine. The specimens were positioned between two testing platens, as shown in Figure 3 (a). The bottom platen was fixed while the upper platen was mounted on a half sphere bearing which could rotate, providing full contact between the platen and the specimens. A 51 mm rigid steel plate was inserted between the upper platen and the specimens. The load was applied through the theoretical centroidal axis of the specimens at a stroke rate of 0.8 mm/min resulting in failure within 2.5 to 3 minutes.

The behaviour of the specimens was monitored through four Linear Variable Displacement Transducers (LVDTs) and a set of six 30 mm long strain gauges. The LVTDs were equally spaced along the bottom half of one flange, 10 mm for the edge of the flange, as shown in Figure 3 (b). The strain gauges were located in pairs on both faces of the opposite flange, 35mm from the flange edge, as well as on the outside face of the web, along its centreline, as shown in Figure 3 (b). The LVDTS aimed to capture the buckling shape of the flange, while the strain gauges aimed to capture the variation in axial and bending strain in the specimens.



(a) (b)

Figure 3 (a) Stub-column test setup (b) LVDTs and strain gauges locations used throughout testing

STUB-COLUMN TEST RESULTS

The maximum load and apparent compressive Modulus of Rupture, $MOR_{apparent}$, of each cross-section is given in Table 2, the latter being calculated based on the measured cross-sectional area of the three internal layers that are resisting the compressive load. The efficiency of the sections, defined as the ratio between the apparent compressive MOR of the cross-section and the compressive MOR of the material (MOR_{wood}) (i.e. representing the upper bound apparent compressive strength of the cross-section and given in Table 1) is also given in Table 2.

Table 2 Stub-column test results

Specimen	Cross-sectional Area[(1)] (mm^2)	Maximum compressive load (kN)	Apparent MOR ($MOR_{apparent}$)(MPa)	Efficiency ($MOR_{apparent}$ /MOR_{wood})
FRP-timber No. 1	1,047	33.5	32.0	0.62
FRP-timber No. 2	1,029	37.3	36.2	0.62
FRP-timber No. 3	1,045	29.7	28.4	0.60
Average	--	--	***32.2***	***0.62***
Full timber No. 1	1,081	26.9	24.9	0.48
Full timber No. 2	1,015	26.6	26.2	0.52
Average	--	--	***25.6***	***0.50***

[(1)] Measured cross-sectional of internal layers only

Table 2 identifies that replacing the external timber layers with FRP increases the efficiency of the sections by 23.2% on average where the FRP-timber and full timber section's efficiency was 0.62 and 0.5 respectively. In comparison, the lipped Cee-sections (without web stiffener) investigated in Gilbert et al. (2014) had an average efficiency of 0.58. Therefore the lipped sections were 16% more efficient than the full timber sections and 7% less efficient than the FRP-timber sections investigated in this paper. For comparison, the lipped cee-sections used 36% more material than the sections investigated in this study.

Figure 4 and Figure 5 plot the recorded displacements of the four LVDTs for timber specimen No. 2 and FRP-timber specimen No. 2, respectively. These figures show that local buckling occurs at a higher applied load (67% higher) for the FRP-timber section than for the timber section, resulting in a higher ultimate load. For the FRP-timber sections, about 55% of the ultimate load was reached before local buckling occurred within the sections, against 42% for the timber sections.

The strain gauge readings for FRP-timber specimen No.1 are shown in Figure 6. The initial difference in stiffness of the strain gauge readings are due to bending of the walls from the geometric imperfections within each specimen. Elastic local buckling starts at approximately 20 kN. The axial strain (ε_{axial}) in the flanges of the

specimen, obtained by averaging the strain readings from strain gauge pairs (see Figure 3 (b)), is plotted for FRP-timber specimen No 1 and timber specimen No 2 in Figure 7 and Figure 8, respectively. These figures also identify the bending strain in the flanges, equal to half the difference of the strain readings from gauge pairs (assuming perfect bonding between plies).

The axial strain in both specimens remains linear until failure indicating that the load is evenly distributed through the entire cross-section until failure. The contribution of the bending to ultimate failure is demonstrated in Figure 8 and Figure 7 where the bending strain caused by local buckling is 290 to 330% higher than the axial strain at failure. Until 64.2% of the ultimate load for the FRP timber specimen No. 1 and 55.7% for the timber specimen No. 2, the axial stress in the flanges is greater than the bending stress, however after this point, the stress induced in the external layers is primarily due to local buckling.

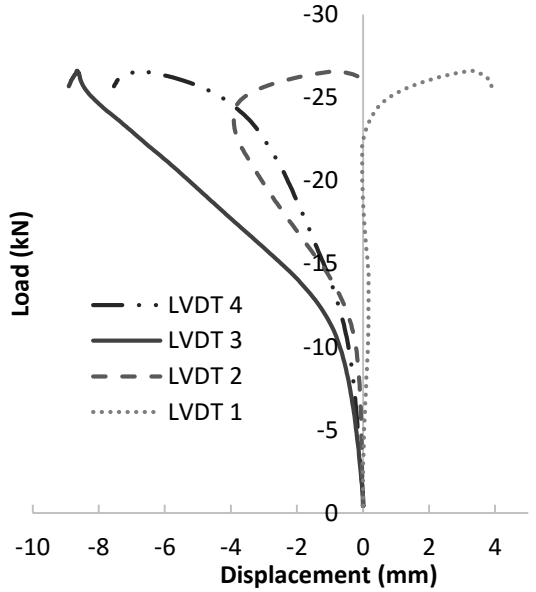


Figure 4 Displacement results from timber section No. 2

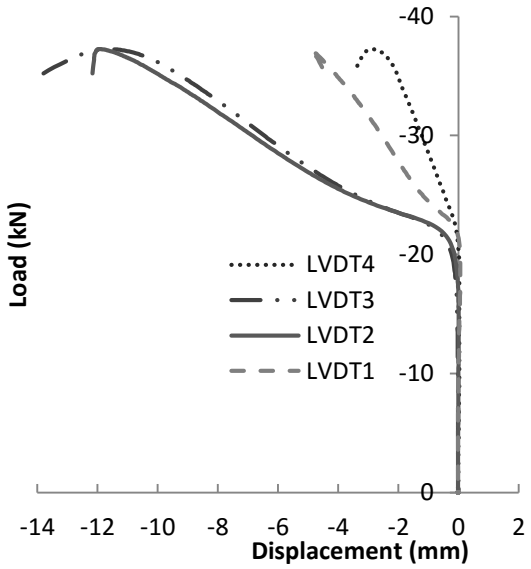

Figure 5 Displacement results from FRP-timber section No. 2

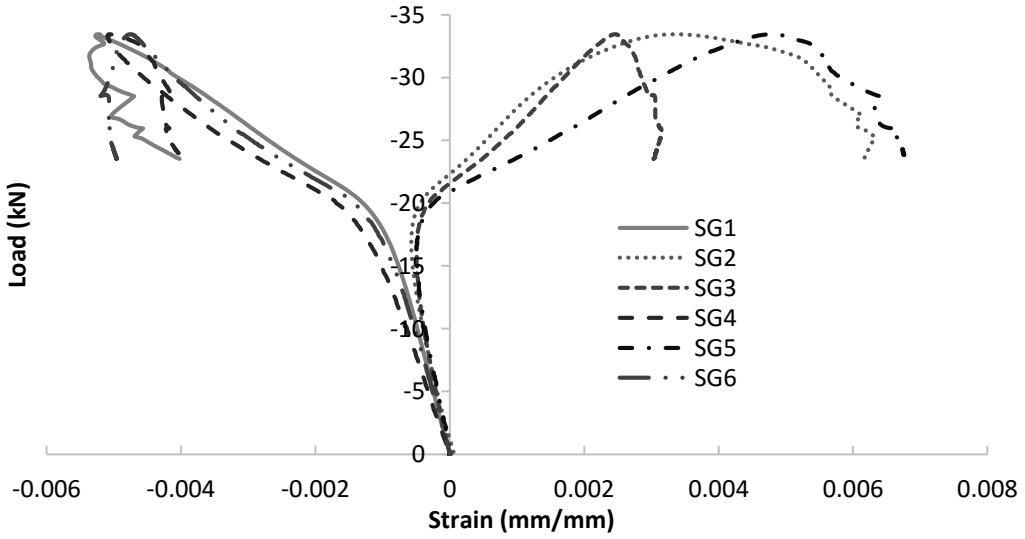

Figure 6 Strain gauge readings for FRP-timber specimen No. 1

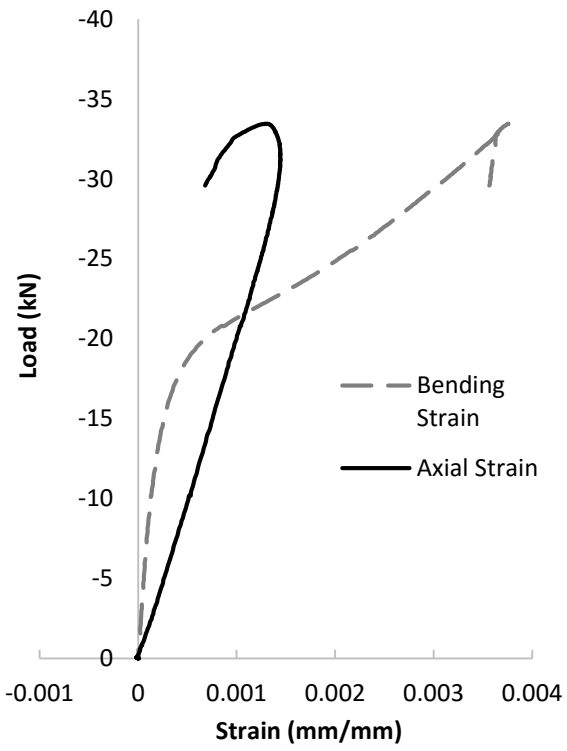

Figure 7 Axial and bending strain of FRP-timber specimen No 1 in the lower half of flange (strain gauges 3 and 4)

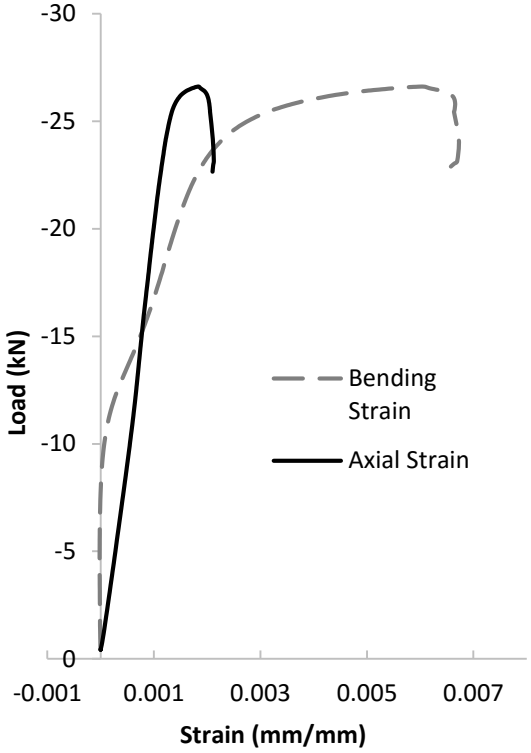

Figure 8 Axial and bending strain of timber specimen No 2 at midpoint of flange (strain gauges 1 and 2)

Two types of local buckling deformed shapes were observed for the FRP-timber sections; FRP-timber specimen No. 3 buckled asymmetrically (with limited buckling of the flange at mid-height (LVDT 4)) as shown in Figure 9 (a), while specimens No. 1 and 2 buckled symmetrically (i.e. large deflections at mid-height), as shown in Figure 9 (b). All FRP-timber sections ultimately failed in the flanges due to bending of the timber layers (see Figure 10). As failure solely occurred in the timber, the thickness of FRP was likely overdesigned and could be optimised in the future, providing it does impact of the FRP's ability to enhance the local buckling capacity of the profiles. This will in turn result in reducing the cost and weight of the specimens.

The two buckling modes discussed above were also observed in the timber sections where timber specimen No. 2 buckled asymmetrically while timber specimen No. 1 buckled symmetrically. Additionally, two distinct types of failure modes were observed for the timber sections. One flange of specimen No. 1 failed in bending at mid-height as shown in Figure 11, while the second specimen had failure ultimately occurring with tearing of the timber at the corner (see Figure 12), a likely cause of the asymmetrical buckling.

The FRP-timber and timber sections had an average measured mass of 1.40 kg and 1.22 kg per unit length, respectively. This corresponds to a weight-to-capacity ratio for the FRP-timber specimens being just 4% less that for the timber sections. However, as discussed previously, it is likely that the amount of GFRP used can be reduced and therefore the FRP-timber sections have the potential to be more efficient sections in terms of weight-to-capacity ratio than the timber ones.

CONCLUSION

The manufacturing issues of thin-walled timber sections encountered in Gilbert et al. (2014) were addressed in this paper and the new manufacturing process was introduced. Thin-walled FRP-timber and timber sections were manufactured and the replacement of the timber cross banded veneers with GFRP was found to significantly simplify the manufacturing process. The sections were tested in compression and the use of GFRP for the cross banded layers was shown to increase the loading efficiency of the sections by an average of 23.6%. The elastic buckling load was also increased. The two section types were comparable in performance in terms of weight-to-capacity ratio. This paper has established that the manufacture of efficient FRP-timber sections is possible and provides a pathway for sustainable and lightweight structural elements.

ACQ-TREATED VENEER BASED COMPOSITE (VBC) HARDWOOD HOLLOW UTILITY POLES FROM MID-ROTATION PLANTATION THINNED TREES: LIFE CYCLE GHG EMISSIONS

ABSTRACT

Hardwood plantations are slow to mature with low financial returns in the early stage. Veneer Based Composite (VBC) products from mid-rotation plantation thinned trees are currently being developed at Griffith University in partnership with the Salisbury Research Centre, Queensland Government, which may offer an opportunity to improve the industry's profitability and win new markets. Due to shortage in utility solid hardwood poles, VBC poles are proposed as a potential alternative. In this study, greenhouse gas emissions of alkaline copper quaternary (ACQ) preservative-treated VBC pole was assessed using 'cradle to grave' life cycle assessment methodology. ACQ preservative was used to extend the service life of wood poles due to wood products are commonly to be degraded in wet environments subject to microbial or insect attack. The manufacturing process considered in this study is based on the current technologies in Salisbury Research Centre. Two (2) end-of-life scenarios were considered: landfilling and incineration with energy recovery. The function unit was a 1-metre-length pole with 115mm internal-diameter and 15mm wall-thickness. Global warming potential (GWP100) was calculated using the IPCC 2007 method. Results indicated disposal stage contributed the most impact. Incineration with energy recovery had the lowest GWP impact (0.337kg-CO_2-Eq) followed by landfilling. Transportation distance was identified as a significant parameter affecting the result. Sensitivity analysis indicated that increasing the transportation distance by 100 km would increase the GWP100 by 21% in the incineration option.

INTRODUCTION

During the last decade, Australian hardwood plantations have increased by approximately 150% with total area of two million hectares, while 49% of this total is managed as hardwood plantations (Australian Government Department of Agriculture Fisheries and Forestry, 2010). Timber plantations present an opportunity to increase Australian long-term wood supply, while contributing to significant social, economic and environmental values (Australian Government Department of Agriculture Fisheries and Forestry, 2014). As it is essential to produce high quality logs at an early age (30 to 35 years), pruning and thinning are required during the early stage of the plantation to ensure sufficient light, moisture and nutrients are available for the rest of the trees (McGavin et al., 2006). Approximately 50% of the trees are typically cut from the third year during the first thinning, with another 30% removed in the second thinning (10 to 15 years). The removed trees during the second thinning (mid-rotation) are usually considered as low commercial value products due to no viable markets (Underhill et al., 2014). Recently, Veneer Based Composite (VBC) products have been developed at Griffith University in partnership with the Salisbury Research Centre (SRC), Queensland Government, from the logs cut during the plantation second thinning as high value applications (Underhill et al., 2014). These products can be applied to replace various engineered wood products (McGavin et al., 2006; Underhill et al., 2014).

Utility pole is defined as a column to support various public utilities, such as cable, fibre optic cable, and related equipment such as streetlights. These poles are usually sourced from native forest hardwood species (Gilbert et al., 2014). Hardwood is usually seen as the most appropriate solution for manufacturing these poles compared to the alternative materials, such as steel and concrete (Francis & Norton, 2006). However, due to the growing

environmental awareness and concerns over the sustainability of forestry practices, agreements have been signed in Australia to phase out logging of native forests. Thus, the supply of hardwood utility poles will decrease sharply (Francis & Norton, 2006). At the same time, the demand for utility poles has increased (Australian Government, Department of Agriculture Fisheries and Forestry, 2014).

The new developed VBC hardwood hollow utility pole presents an alternative to replace traditional hardwood poles (Gilbert et al., 2014), while offering positive environmental and economic. Untreated wood products are easy to degrade in either weather-exposed or wet environments subject to microbial or insect attack (Ibach, 1999), chemical preservation is usually used to extend the service life of wood products (Morrell, 2004). Alkaline copper quaternary (ACQ) is one of the most commonly used preservatives for treating timber products (Bolin & Smith, 2011). Nevertheless, the sustainability of the product in terms of life cycle perspective needs to be established. For this reason, LCA is developed in this paper to assess the environmental performance of the ACQ-treated VBC hardwood hollow utility poles manufactured from mid-rotation hardwood plantation thinned trees.

This paper aims to conduct a LCA study to investigate the environmental performances associated with ACQ-treated VBC hardwood hollow utility poles manufactured from Gympie messmate (*Eucalyptus cloeziana)* mid-rotation plantation thinned trees. The environmental burdens of two different disposal scenarios are assessed to determine appropriate end-of-life treatment. Results of this study might have implications for hardwood plantation owners and utility companies to facilitate a better sustainable management of plantations and utilities networks.

METHODS

The goal of this study is to provide a scientifically based and comprehensive assessment of the environmental performance of the VBC hardwood hollow utility pole manufactured from mid-rotation hardwood plantation thinned trees over its life cycle. The scope of this study includes 'cradle to grave' life cycle inventory of the VBC hollow utility poles. The timbers are obtained from the hardwood plantation located in Queensland. LCI data are collected from AusLCI database, as well as published sources.

For collection of life cycle inventory inputs and outputs, small diameter poles, of 1 meter in length, with nominal internal diameter of 115 mm and 15 mm wall-thickness is assessed as one functional unit. The VBC utility poles are constructed from two half-poles jointed together, while each half pole manufactured from gluing nine veneers. The poles are similar to the ones tested in (Gilbert et al., 2014) and the manufacturing process is detailed in (Underhill et al., 2014).

The system boundary begins with hardwood seedling and ends with the VBC poles being deposited in landfill, recycled or reused. Planting the seedlings, forest management (i.e. site preparation, first thinning and fertilisation), and second thinning are considered in the system boundary of plantation. Transporting thinned logs from the plantation site to the mill is accounted for the pole manufacturing. Seedlings, fertiliser and energy consumptions are considered as inputs in the first stage. The VBC timber pole manufacturing process are divided into several small process units: transportation, debarking and cutting, pre-conditioning, logs peeling, veneer drying, compressing, trimming, VBC utility pole forming, and transporting to the utility lines. The final stage includes pole services in utility system and final disposal (e.g. landfilling and incineration for energy recovery). The system boundary is presented in **Figure 1**. As the thinned log is a by-product from the forestry industry, allocation is required. In this study, economic allocation was used following May et al. (2012). In economic allocation, impacts were distributed among co-products according to their market value.

The global warming potential (GWP100) is investigated in this LCA. OpenLCA software was used to conduct the LCA analysis (GreenDelta, 2014). IPCC 2007 life cycle impact assessment (LCIA) method was used for the characterisation of emissions into the relevant impact category.

LIFE CYCLE INVENTORY (LCI)

The inventory analysis involves data collection and analysis for the cradle-to-grave life cycle of the VBC utility poles. For each stage of the product life cycle, inputs of energy and raw materials, outputs of products, waste, and emissions releases to environment are determined. In addition, hardwood plantation system is assumed in a steady state both with respect to carbon stocks and management operations. This assumption has been used either explicitly or implicitly in most other forestry LCIs (e.g. Schweinle & Thoroe, 1997; Seppala et al., 1998;

Sonne, 2006, Dias et al., 2007). Life cycle inventory (LCI) data are collected from different sources, including published literature and the Australian National Life Cycle Inventory (AusLCI, 2011).

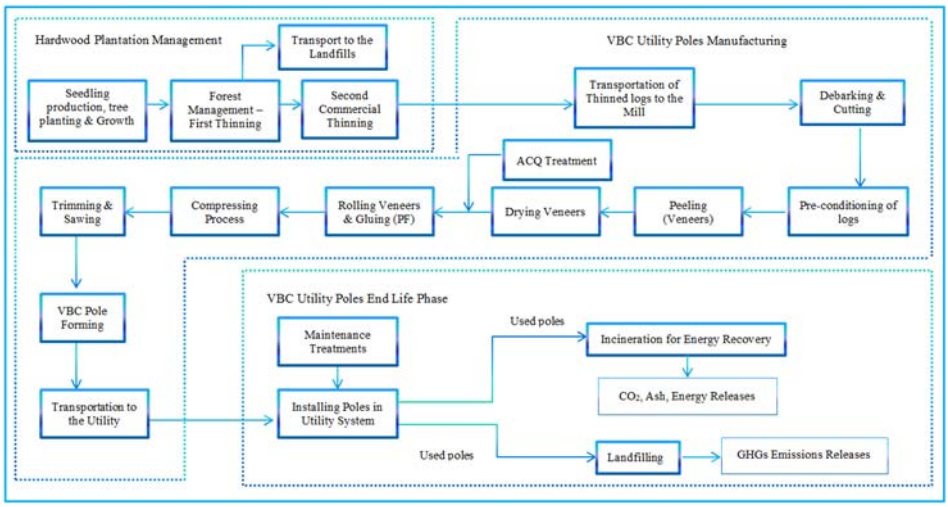

Figure 1 System boundary of VBC pole

Hardwood Plantation Operations

The specific processes during establishment include seedling production, site preparation, slash burning (burning of residues) and planting. Management process includes chemical application of herbicides or fertiliser, fire prevention and control and construction of forest roads. Thinning process starts from first thinning to second commercial thinning. The electricity consumption for greenhouse operations, fertiliser used for seedling production and growth, and the diesel fuel and lubricants required to power equipment during site preparation, fertilisation, and thinning are considered as the inputs. The primary output in this analysis is the green logs from second thinning. The other products, such as non-merchantable slash and brunches are usually treated by mechanical activities or prescribed fire on site, which is not included in the system boundary. Table 1 presents a summary of materials and energy consumption of hardwood plantation.

Table 1 Average fuel and materials consumptions of hardwood plantation per m^3 in QLD region (sourced from May et al., 2012)

Inputs Energy & Materials	Unit	Quantity

VBC Utility Poles Manufacturing

In order to extend the service life of VBC poles, ACQ treatment is assumed in this LCA. The ACQ-treated VBC utility poles manufacturing process are based on current technology used at the Salisbury Research Facility and the LCI data is collected from different published sources.

The production of one function unit of hardwood VBC pole consumes 0.0142 m^3 of green logs. The main inputs considered in the LCI analysis are the hardwood logs from second thinning into the veneer process, leading to

veneer input into the VBC process. The logs are green and include wood and bark with moisture content of approximate 50%. The main inputs to manufacture one functional unit of average Australian VBC pole are listed in Table 2.

Table 2. Inputs and outputs to produce one functional units of VBC pole average Australian veneer based composite including energy from veneer production (adapted from Ayres, Ayres & Rade, 2003; Tucker et al. 2009; Wilson, 2009; Puettmann et al., 2013).

Material Inputs	Value/function unit	Unit

VBC Utility Pole Service Life

The ACQ-treated VBC utility pole service stage includes transportation of pole, installation, and maintenance during its service life. Steel bolts used to attach the VBC poles and other hardware are installed by the utility, but they are not considered in the LCI analysis due to steel bolts used to mount cross-arms generally are the same for all poles (Bolin & Smith, 2011).

An average distance of 100 km is assumed for pole transportation, which translates to 0.37 tkm per functional unit of pole. Transportation data are sourced from AusLCI database (AusLCI, 2011). An average service life of 25 years is assumed for VBC poles according to the survey conducted by the Salisbury Research Centre (H. Bailleres, personal communication, December 22, 2014). Most utility poles have regular inspection programs around 8 to 12 years (Mankowski, Hansen & Morrell, 2002). An inspection and maintenance program is included in this LCI. Each pole is assumed to be inspected and maintained every 10 years. The treatment model assumes that 0.069 litres/pole of paste is needed per treatment, consisting 2% of copper, 43% borate (DOT), 10% petroleum (as a surrogate for other possible fossil fuel derived ingredients), water, and mineral filler/thickeners. Based on data published by Bolin & Smith (2011), the treatment per functional unit consists of 0.0014 L copper, 0.0297 L borate and 0.0069 L petroleum.

End of Service Life

At the end of service life, poles may have recycling value as treated wood, such as fence posts or landscaping or as fuel to produce process heat and/or electricity. Some utility companies also simply dispose of the used poles as solid waste in landfills. In this study only landfilling and incineration with energy recovery are considered.

Scenario I – landfilling

Disposal stage begins with the poles transport to landfill and includes processing of the landfilling, as well as emissions release. Collection and transportation distance between utility lines and landfill is assumed as approximately 100 km. The landfilling results in 40.164 kg of wood carbon released as carbon dioxide, while 8.453kg of methane released per 1000 kg of wood waste (AusLCI, 2011). At landfills with a CH_4 capture infrastructure, typically up to 75 % of the CH_4 generated is assumed to be captured by the collection system (Ramseur et al., 2009). An analysis of the primary metal components in the wood conducted by Dubey et al.

(2009) indicated that copper and boron concentrations in the ACQ-treated wood samples were 3750+/-125 mg Cu/kg and 510+/-35 mg B/kg. These concentrations are consistent with the manufacturer rated concentration of 4 kg/m^3 (kilogram of total metal oxide components per cubic meter of treated wood).

The landfilling considered in this study includes 100 years of product life after disposal. This time frame is consistent with other solid waste studies (e.g. Diaz & Warith, 2006; El Hanandeh & El-Zein, 2010). The LCI of landfill construction and closure is adopted from Mènard et al. (2003). Landfilling emission outputs data of wood waste is sourced from AusLCI database (AusLCI, 2011). The LCI data for VBC pole in landfill is shown in Table 3.

Table 3. LCI data for wood waste in landfill in QLD region per functional unit (adapted from Mènard et al., 2003; Dubey et al. 2009; AusLCI, 2011)

Input Flow	Value/function unit	Units
Wood and wood-waste, at landfill	3.71	kg
Electricity, low voltage, Australian	0.003	kWh
Transportation	0.371	tkm
Diesel, burned in building machine/GLO U	0.143	MJ
Output Flow	Value	Units
Carbon dioxide, biogenic	0.149	kg
Methane, biogenic	0.031	kg
Non-methane volatile organic compounds, unspecified origin	0.014	kg
Copper	0.015	kg
Boron	0.002	kg

Scenario II – combustion for power generation

VBC Poles recycled for power generation are assumed to be combusted in large cogenerations that include electrostatic precipitators. The transportation distance is assumed 100 km to power plant. During the energy recovery, the wood carbon is released as biogenic carbon dioxide and the combusted preservative carbon will be released as fossil carbon dioxide (Bolin & Smith, 2011). Lin et al. (2007) investigated the ACQ-treated woods during combustion and noted that the released CO gas was about 179.3 ppm. The maximum NO_x of the ACQ treated wood was about 23.5-26.5 ppm. By clarifying the residual elements of discarded ACQ treated wood products; the results indicated the char of the ACQ left an amount of inorganic metal elements, Cu (50.14%) (Lee et al., 2005; Lin et al., 2006). The other components of ACQ were volatilized with the increase in temperature during combustion (Lin et al., 2007).

The LCI of wood waste incineration is based on Australian published sources. The utilities used in the waste incineration plant, the bottom ash from incineration and air pollution residues are included in the system. The bottom ash (approximately 220kg/Mg of treated wood product) is disposed in landfill. The energy recovery through wood waste combustion is modelled as energy credit due to the avoidance of production of materials from virgin feedstock (coal and natural gas) and the gains of electricity. The energy content of wood waste is assumed to be 9.5MJ/kg, while the efficiency of power generation for wood waste is 20% based on NSW Environment Protection Authority (2012). Thus, 10.57MJ of electricity is generated per functional unit of utility pole, while the heat waste is approximately 24.67MJ/functional unit. The LCI data of ACQ-treated wood in incineration is presented in table 4.

Table 4. LCI data of wood waste for energy generation in QLD region per functional unit (adapted from Lin et al. 2007; Ximenes, Robinson &Wright, 2007; Tucker et al., 2009; DCCEE, 2011a,b; NSW Environment Protection Authority, 2012)

Input Flow	Value/ Function Unit	Units/Pole
Wood and wood-waste	3.71	kg
Transportation	0.453	kg
Output Flow		
Electricity	10.57	MJ
Heat, waste	24.67	MJ
Carbon dioxide, biogenic	6.056	kg
Nitrogen dioxide	0.004	kg
CO	0.001	kg
NO_x	0.0001	kg

Cu	0.012	kg
Bottom ash	0.816	kg

RESULTS, ANALYSIS AND DISCUSSION

To assess the processes that result in GWP100 from ACQ-treated VBC utility poles, impact indicator values are added to the entire life cycle stages. The results show that incineration with energy recovery option (0.337 kg $CO_{2\ eq}$) out-performs the landfilling option (2.784 kg $CO_{2\ eq}$) with respect to GWP100 impact. This is mainly due to avoided methane release from the landfill.

Bolin & Smith (2011) conducted a LCA to compare the environmental impacts of pentachlorophenol (Penta) treated solid wooden utility pole to steel and concrete poles. Our study indicates that VBC hollow poles may have higher environmental burdens than penta-treated softwood solid pole when considering landfilling as end of life treatment. On the other hand, the impacts of the VBC poles may be reduced if incineration with power generation is used for disposal. Results of this study also indicate the GWP100 potential of VBC utility poles is lower than similar standard concrete poles (7.225 kg CO2-eq per functional unit) and steel poles (3.68 kg CO2-eq per functional unit) (Bolin & Smith, 2011). That is mainly because fewer raw materials are required for casting VBC poles. Furthermore, the hollow structure makes VBC poles lighter, hence less transportation emissions compared to the much heavier concrete poles. Additionally, during the manufacture of ACQ-treated VBC utility poles, fossil fuel is mostly substituted by wood fuel (wood waste) that burn in the boiler for heating, thus avoiding the GHG emissions generation.

Figure 2 presents the percentage contribution to GHG emissions of each stage during of the two EOL scenarios. Thinned logs, VBC poles in service and the final disposal stages contribute most of the environmental impacts under GWP100, particularly due to transportation, PF resin production and GHGs emissions release during wood decay. Specifically:

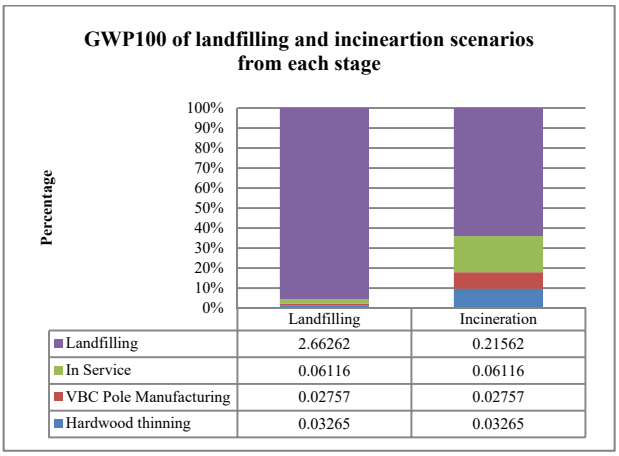

Figure 2 Comparison of emissions from different life stages of each scenario

- In the landfill, approximately 95% of GHG emissions result at the end of the life cycle stage mainly caused by methane release from decay of the treated wood, as well as CO_2 from transportation. However, this result is subject to the assumptions, especially related to GHGs emissions generation and capture. Meanwhile, during the incineration approximately 65% of GHG emissions result at the end of life cycle stage mainly due to waste transportation and GHGs emission generation.
- Natural gas and diesel fuel inputs to the treated VBC pole life cycle mostly mainly occur in the pole manufacturing stage. Approximately 22% of GHG emissions result from the natural gas and diesel fuel combustion due to the veneer pre-conditioning, drying, and compressing process during the manufacturing.
- PF resin manufacturing contributes to 33% of the emissions potentially resulting in GWP100 mainly due to transportation of raw materials.

Sensitivity Analysis

Sensitivity analysis is completed to determine the effects of assumptions change on LCA results. Items or categories, which show high sensitivity effect on impact indicator, are discussed in details below. Additional

information and model results are included.

PF resin

PF resin consumption in VBC products is adjusted due to the different manufacturing technologies available. The baseline used in this assessment is 53.6kg/m^3. Two cases are modelled for sensitivity analysis, including: 1) at 10kg/m^3 and 2) at 60kg/m^3. For landfilling option, increasing the PF resin consumption from 10 to 60kg/m^3 is not significantly affecting the GWP100, which only increases by 2% in total due to the final disposal contains extremely high contribution of GWP100. Meanwhile, increasing the PF resin consumption, from 10 to 60kg/m^3 results in total GWP100 rises by 46% (shown in **Figure 3**).

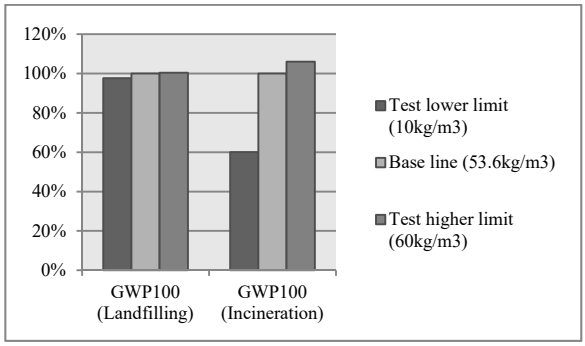

Figure 3 Sensitivity analysis for landfilling and incineration scenarios: PF resin production and consumption

Transportation

In this study, transportation distance of products from manufacturing facility to the utility system is assumed to be 100 km per functional unit with 10% return load. However, distances in the range of 50 -150 km are reported. As expected, changing the transportation distance from 50 km to 150 km only increases the total GWP100 by 1% in landfilling scenario. In the case of incineration, it results in increasing GWP100 by 21% (shown in **Figure 4**).

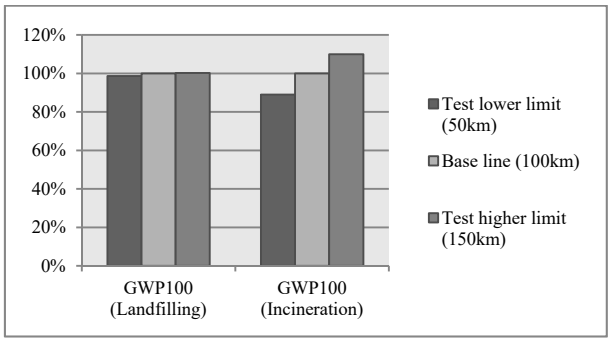

Figure 4 Sensitivity analysis for landfilling and incineration scenarios: transportation distances

Landfilling Disposal

This LCA assumes that 77% of the carbon absorbed by the wood is sequestered after decomposition in landfill, as reported in Barlaz (1998). However, preservative and other inorganic compounds in the disposed wood are expected to retard carbon release when compared to untreated wood (Bolin and Smith, 2011). Two cases are modelled for sensitivity; 50% and 90% of sequestered carbon. The results show that a higher sequestration percentage reduces the GWP impact indicator by approximately 14%, while reducing the sequestration percentage to 50% increases the GWP impact by 30% when compared to the baseline model (**shown in Figure 5**). Nevertheless, a field investigation of wood decay in Australian landfills revealed that wood deposited in landfills have remained virtually intact (Ximenes et al., 2015). Therefore, it is most likely that the GWP of the landfilling option is much smaller than what is predicted in this LCA study.

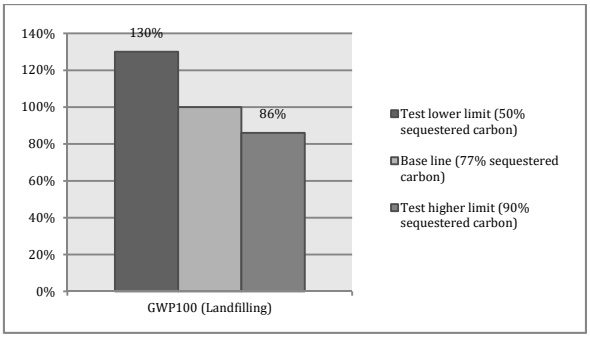

Figure 5 Sensitivity analysis for landfilling scenario: landfilling disposal

Limitations

The scope of the study is limited to boundaries established in the goal and scope documented in this study. Limitations included reliance on published and publically available information in many instances. Such information is assumed to be accurate. The life cycle inventory completed for VBC pole manufacturing is designed to represent the typical poles for traffic light. Nevertheless, the impact of manufacturing the VBC poles may vary according to the technology and scale used. Inventory data for the wood waste disposal are sourced from the Australian LCI database. This study only assessed the GWP100, other impact indicators are not considered. Additionally, the life cycle cost was not evaluated in this study. Further studies using life cycle costing is needed to gain comprehensive understanding of the system. This LCA focused on ACQ-treated VBC poles. While portions of this LCA may apply to poles treated with other preservatives, the overall conclusions only apply to ACQ-treated VBC products.

CONCLUSION

This LCA study assessed the environmental impact of ACQ-treated VBC hollow poles using life cycle methodology. Two disposal scenarios, landfilling and incineration, for end of life treatment were considered. The incineration option presented a better environmental performance than landfilling, mainly due to the avoidance of methane release during the disposal stage. In addition, the energy recovery through wood waste combustion is seen as an energy credit, which offered positive environmental benefit to the incineration scenario. Long distance transportation and fossil fuel consumption due to the thinning process, pole manufacturing and service in utility system were also identified as the main contributors to the GWP100.

This study focuses solely on the environmental performance of the VBC poles. It is recommends that the economic and technical feasibility of the poles and the alternatives should be considered. Further research is required to evaluate the environmental, economic and social impacts to achieve comprehensive understanding of the viability of the proposed VBC hollow utility poles as an alternative solution to hardwood poles for the Australian utility network.

ABSTRACT

Cross Laminated Timber (CLT) construction is now considered a viable and sustainable alternative to traditional building techniques within the multi-storey building sector. This is primarily due to the high level of prefabrication possible with CLT construction, its high strength-to-weight ratio and its potential as a carbon negative building material. As a result, an increasing number of developers and architects are requesting a CLT design option for multi-storey buildings using CLT wall and floor panels. The latter, especially long span floors, provides a challenge for engineers. Long span CLT floors have a lower natural frequency and are light in weight, which can cause noticeable vibrations. This paper examines existing analytical design procedures available to calculate floor vibrations and provides a preliminary design for floors spanning 9 m. Innovations in CLT panels are introduced, including increased connection rigidity and the use of hardwood timber species, resulting in increased panel stiffness and reduced floor vibrations. Whilst CLT has been extensively researched and tested in Europe and Canada, only limited research has occurred within Australia and New Zealand. This paper also discusses Australian and New Zealand standards and codes and the use of locally grown soft and hardwood timber species for CLT panels.

KEYWORDS

Cross Laminated Timber, Sustainable Materials, Floor Dynamics, Long Span Floors, Structural Design

INTRODUCTION

Vibration design has become an important design parameter for timber floors due to the increasing demand for longer spans and lighter structures for commercial buildings. For timber floors over 4 m, the floor design is generally governed by ensuring acceptable levels of vibration (Thiel 2013). Current market trends indicate the need for timber floor solutions to satisfy a 9 x 9 m floor grid to ensure competitiveness with concrete and steel construction. The criteria of a 9 m spanning floor allows for open plan office spaces and efficient parking arrangements between columns required by commercial buildings.

Cross laminated timber (CLT) is a slab like engineered wood product composed of a number of panels of sawn lumber glued and pressed together, with each layer orientated orthogonal to the adjacent layer (Figure 1). The multi-storey timber building market is currently expanding, with several existing examples of CLT buildings up to 12 storeys and more currently in the planning process (Brandner 2013). To span a 9 m floor with CLT panels is challenging as the product will lose its edge over traditional concrete slab design if the weight or thickness of the panel required to satisfy vibration design becomes too large. Accurate vibration design and specifications are therefore essential for ensuring an optimised floor layout.

Vibration design guidelines from Australian standards and codes are currently limited. AS1170.0 (2002) provides a static unit deflection limit, requiring the deflection of a floor under a mid-span unit point load of a maximum 1-2 mm. Specifically, in the timber design standard AS 1720.1 (2010) attention is drawn to the fact that “deflection limits do not necessarily ensure satisfactory dynamic performance”, however no other guidelines are given. Reference is made to AS 2670 (2001) which provides acceptability limits in the form of root mean square (RMS) accelerations, however this does not provide analytical equations for the vibration design of the floor layout.

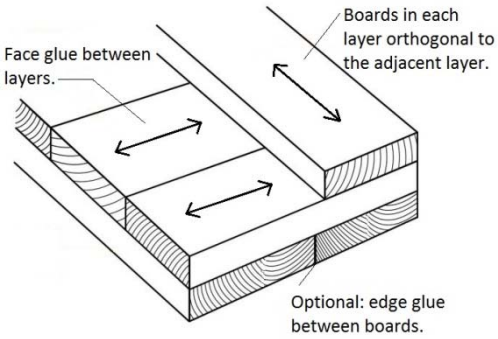

Figure 1 Layout of cross laminated timber.

A number of analytical methods for modelling vibrations have been developed and expanded in both Europe and Canada. These methods provide calculations and limits for natural frequency, unit deflection, velocity and acceleration of CLT floors. The limit for frequency is based on avoiding resonance with walking (around 3Hz) and a comprehensive study of more than 100 problematic floors that were found to have a frequency range of 5-8 Hz (Murray et al. 1997). Eurocode 5 provides calculations that allow a minimum natural frequency of 8 Hz. However, further studies by Hamm et al, (2010), on floors of 50 existing buildings found some floors with natural frequencies over 8 Hz, particularly the lighter floors, did not satisfy acceptable vibrations while a number of floors with natural frequencies between 5-8 Hz had acceptable vibration performance. The study found that the stiffness and the acceleration of the floor were also important parameters and provided an extension to the Eurocode 5 method that allowed floor natural frequencies below 8 Hz.

Parameters that affect the vibration performance of a floor include stiffness, damping and mass as well as the support rigidity and any two-way action from CLT that can be utilised (Weckendorf et al. 2008). This paper investigates the effect of varying stiffness, support conditions and two-way action, on the preliminary design of a cross laminated timber floor spanning 9 m. This paper also provides a comparison of the analytical methods that have been developed for calculating the vibration performance of a timber floor and demonstrates that these methods provide vastly different design solutions due to the subjective nature of the design limits.

Finally the paper considers material properties satisfying F-grades in accordance with AS1720.1 (2010), since both structural and non-structural Australian *Pinus Radiata* have shown promise for use as CLT panels (Sigrist & Lehmann 2014).

FLOOR PROPERTIES

The preliminary design for the 9 m panel was sized to satisfy strength and both short and long term deflections. Two panels were chosen for preliminary analysis: an 8 layer CLT panel (Floor 1) with a high stiffness in the longitudinal direction and a 7 layer CLT panel (Floor 2) with a lower stiffness longitudinally but with a higher transverse stiffness (Figure 2). Material was kept constant between the two; using F11 graded seasoned softwood timber with a density of 550 kg/m^3, similar to grades of commercially available CLT panels.

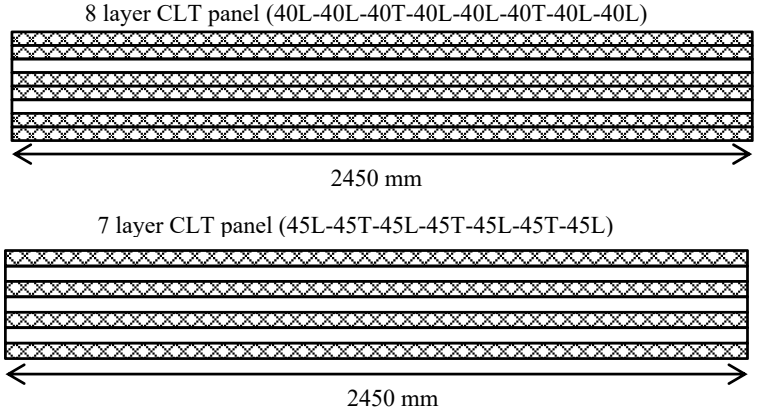

Figure 2 Cross sections of CLT panels for preliminary design. Top: Floor 1, 8 layered CLT panel, 320 mm thick. Bottom: Floor 2, 7 layered CLT panel, 335 mm thick.

There are a number of methods for calculating the effective section modulus, EI_{eff}, of a cross laminated timber panel. These have been developed based on mechanically jointed beam theory to take into account the decrease in stiffness due to the shear slip caused by the transverse layers. The CLT Handbook by FPInnovations provides a comprehensive outline, including worked examples of these methods (Gagnon & Popovski 2011). This study considers the Gamma method as outlined by Eurocode 5, however, all the methods provide accuracy of effective stiffness for ratios of span/depth over 15 (Thiel & Schickhofer 2010).

Since the floor is to comply with Australian Standards for commercial flooring, the live load was taken as Q = 3kPa while a superimposed dead load for finishes and services was considered as G_{SI} = 1.5 kPa. According to AS1720.1, a creep factor of j_2 = 2 is used for long term deflections of plywood. Due to the orthogonal arrangement of CLT similar to that of plywood, the panels are prone to time dependent deformations under load, more than other unidirectional products and hence the values have been found to be comparable (Pirvu & Karacabeyli 2014).

The effective stiffness, EI_{eff} of Floor 1 was found to be 59.1 x 10^{12} Nmm^2 while the effective stiffness of Floor 2 was found to be 56.8 x 10^{12} Nmm^2. The values calculated for design bending moment and deflections, including the limits used, are displayed in Table 1. The long term deflection governed the preliminary design of the floor with 87% and 92% acceptability rates for Floor 1 and Floor 2, respectively.

Table 1 The design of CLT panels satisfying strength and deflection limits according to ULS and SLS design.

	Floor 1			Floor 2		
	Design Value	Design Limit	Acceptability	Design Value	Design Limit	Acceptability
Bending Moment (kNm)	1026	208	20%	934	210	22.5%
Deflection Short term G+0.7Q (mm)	18.9	30 (Span/ 300)	63%	19.9	30 (Span/ 300)	66%
Deflection Long term G+0.4Q (mm)	31.4	36 (Span/250)	87%	33.2	36 (Span/250)	92%

ANALYTICAL METHODS

The analytical methods that have been developed to calculate the vibration performance of a CLT floor assess one or more of the following properties; stiffness, natural frequency, velocity and acceleration of the floor. The methods compared in this paper are methods from Eurocode 5 (2008), modifications of Hamm et al. (2010), modification by Mohr (1999) and the CLT Handbook criteria (Hu & Gagnon 2011). These methods and the criteria they use to assess the floor, including limit values are summarised in Table 2.

Table 2 Comparison of available analytical models for determining vibration performance.

	Stiffness (Unit Displacement)		Floor Natural Frequency		Floor Velocity		Acceleration (floors under 8 Hz only)	
Vibration Performance Method	Load kN	Limit mm	Load Case	Limit Hz	Velocity	Limit	Frequency Range Hz	Limit m/s^2
Eurocode 5	1	≤1	G_{TOT}	≥8	(5	(4		
Hamm et al	2	≤0.5	G_{TOT}	≥8			4.5 - 8	≤0.05
Mohr	1	≤1	G_{TOT}+0.3Q	≥8	(9	(9	3.4 - 8	≤0.1
CLT Handbook	1	*	G_{TOT}	*				

*CLT Handbook criteria the floor frequency is dependent on the floor stiffness and vice versus.

The methods from European research and standards (Eurocode 5, Hamm et al. and Mohr) require one to first define the vibration requirements of the floor; normal or high. High requirements are considered for commercial buildings and multi-storey residential blocks, whereas normal requirements are considered for single unit dwellings. Since this research is concerned with long span floors, primarily found in commercial buildings, high requirements for vibration are considered.

CLT is a plate type timber product rather than a linear beam element and therefore this paper considers a 1 m cross section of the panel to determine the effective stiffness ($EI_{eff,1m}$) rather than the entire width of the CLT panel. For calculating the cross sectional stiffness, the methods discussed generally consider only the boards in the longitudinal direction and discount the transverse boards. In doing so, the reduction in cross sectional

stiffness due to the shear slip of the transverse boards is not considered. To date, there has been no agreed upon method for calculating the value of EI, this paper considers both the effective stiffnesss (EI_{eff}) and the longitudinal stiffness (EI_l), depending on the recommendations from the method under consideration.

Eurocode 5

Eurocode 5 provides guidelines for providing acceptable vibration design of residential timber floors. For these calculations, both the longitudinal stiffness (EI_l) and stiffness transverse to the span (EI_t), for a 1 m wide cross section of CLT are used to calculate the natural frequency, deflection limit and floor velocity.

The natural frequency of the timber floor, calculated using (1, is limited to a minimum of 8 Hz, to avoid vibrations caused by resonance. Eurocode states that frequencies of 8 Hz can be acceptable with a "special investigation" required, however, it does not provide guidelines for this investigation (CEN 2008). The factor for support stiffness (k_m) in Eurocode 5 is equal to π^2 which represents a single span simply supported floor. For a fully fixed single span floor the stiffness factor is equal to 22.4 (Thiel 2013).

$$f_1 = \frac{k_m}{2\pi l^2}\sqrt{\frac{(EI)_l}{m}} \geq 8\ Hz \tag{1}$$

The mass, m, is treated as a static mass; equal to the self-weight of the floor plus any extra super imposed weight. Further to checking natural frequency, the deflection due to a unit force ((2) is limited to a maximum value a, which is dependent on the required vibration performance level of the floor. A graph is provided in the code that displays the relationship between the limit value for deflection, a, and the limit value for velocity, b (Figure 3). The calculations are based on a rectangular floor supported on all four sides. Therefore an equivalent beam width, b_{eff}, is calculated to determine the panel's equivalent beam effective stiffness, EI_b, taking into account the transverse stiffness using (3 (Mohr 1999). Since this paper considers floors with higher requirements for vibration, the limit values are taken as a = 1 mm/kN and b = 120.

$$w_{EC5} = \frac{1}{48}\frac{Fl^3}{EI_b} \leq a\ mm/kN \tag{2}$$

$$b_{eff} = \frac{l}{1.1}\sqrt[4]{\frac{EI_t}{EI_l}} \tag{3}$$

The velocity (v) due to an impulse of 1Ns is then calculated using (5 and limited by (4. Only the number of first order modes with natural frequencies up to 40 Hz is considered and calculated using (6. A value for damping, ζ = 1%, is provided by the code. Research has found that for light weight timber floors the first mode of vibration of damping is generally around 2%, however when considering higher modes, the damping can be as low as 0.8% (Weckendorf et al. 2008).

$$v \leq b^{(f_1\zeta-1)}\ m/(Ns^2) \tag{4}$$

$$v = \frac{4(0.4 + 0.6n_{40})}{mbl + 200} \tag{5}$$

$$n_{40} = \left\{\left(\left(\frac{40}{f_1}\right)^2 - 1\right)\left(\frac{b}{l}\right)^4 \frac{(EI)_l}{(EI)_b}\right\}^{0.25} \tag{6}$$

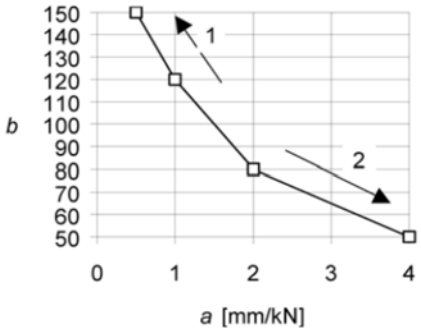

Figure 3 Interaction between the limit values of a, and b; directions 1 and 2 correspond to better and worse behaviour respectively (CEN 208).

Modifications of Hamm et al.

Modifications of the Eurocode 5 method were developed by Hamm et al (2010) in Germany to account for the stricter requirements on vibration performance and for floors with natural frequencies less than 8 Hz. The research, which was based on the assessment of 50 buildings and 100 floors, found timber floors with natural frequencies less than 8 Hz, particularly heavy floors, could have acceptable vibration performance. A light floor on the other hand could perform poorly when subjected to frequencies over 8 Hz. A flow chart that outlines the design procedure is included in Figure 4.

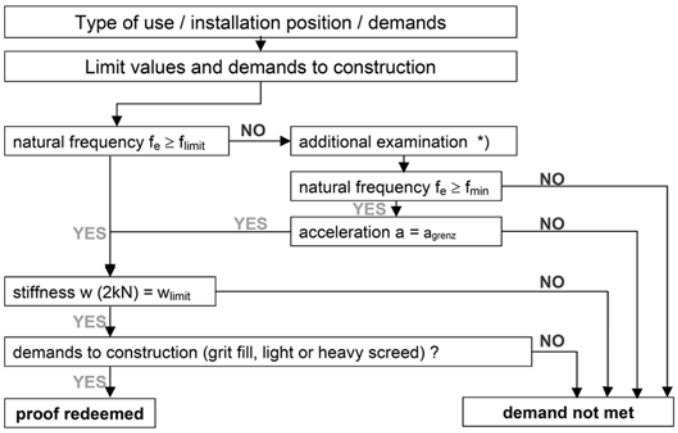

Figure 4 Flow chart for the design and construction of timber floors, the additional examination * only applies for heavy floors with wide spans, or timber concrete composite systems (Hamm et al. 2010).

The frequency is calculated using the same method as Eurocode 5 considering only the static mass of the floor. The stiffness criterion is also calculated using a similar method as the Eurocode, however it is given a more stringent limit value of 0.5 mm and a concentrated load value of 2 kN as opposed to 1 kN. The more stringent criteria were determined by studying the behaviour of a number of floors (Hamm et al. 2010).

If the frequency of the floor is less than 8 Hz, the floor is not necessarily deemed unacceptable, unlike the Eurocode. An additional examination of the acceleration is provided along with the original criteria also being met. The acceleration is calculated using (7 and is limited to 0.05 m/s^2. Where P_0 is the force of one person (taken as 700 N) and the values for the Fourier coefficient α_i and the forcing frequency F_F are given in Table 3. The generalised mass, M_{gen}, is equivalent to half the effective area contributing to vibration performance ((8) where the mass, m, is the self-weight of the floor plus any super-imposed dead load. Values for damping were taken as 1% as outlined by Eurocode 5.

$$a \approx 0.4 \frac{P_0 \alpha_i(f_1)}{M_{gen}} \frac{1}{\sqrt{\left[\left(\frac{f_1}{f_F}\right)^2 - 1\right]^2 + \left(2D\frac{f_1}{F_F}\right)^2}} \leq 0.05\, m/s^2 \tag{7}$$

$$M_{gen} = m\,\frac{l}{2} b_{eff} \tag{8}$$

Table 3 Fourier coefficient, dependent on the fundamental frequency of the floor (Mohr 1999).

Fundamental Frequency Hz	Fourier coefficient	Forcing frequency F_F Hz
$3.4 < f_1 \leq 4.6$	0.2	f_1
$4.6 < f_1 \leq 5.1$	0.2	f_1
$5.1 < f_1 \leq 6.9$	0.06	f_1
$f_1 > 6.9$	0.06	6.9

Mohr Criteria

The International Council for Building Research Studies and Documentation, provides an alternate modification to the Hamm et al. method for frequencies below 8 Hz, and was developed at the Technical University of Munich (Mohr 1999). This method considers a quasi-static floor mass that includes a portion of the live load in the total floor mass (G + 0.3Q) for calculating the natural frequency. Apart from the floor mass being quasi-static,

both the frequency and the floor stiffness are calculated by the same method as Eurocode 5. A floor velocity check is included that was derived from the action of a "heel drop" and is given by (9. A damping value of 1% is assigned to floors without any additional boarding's for sound isolation as outlined by Mohr (1999). While in practice a commercial floor will have either a ceiling or an access floor to provide services and sound insulation, a value of 1% for damping is considered in this paper.

$$v_{MOHR} = \frac{0.6}{m_f^{0.5} EI_l^{0.25} EI_t^{0.25}} < v_{lim,MOHR} = 6 \times 100^{(f\zeta - 1)} \tag{9}$$

For floors with frequency below 8 Hz the acceleration is calculated using the same methods as outlined by Hamm et al. (2010), however the acceleration limit is less stringent at 0.1 m/s^2.

CLT Handbook

A Canadian research team, FPInnovations, developed a simplified method to specifically assess the vibration performance for CLT floors, which was published in the CLT Handbook (Hu & Gagnon 2011). The criterion ((10) provides an inequality based on the fundamental frequency and the effective stiffness of the floor under a unit load.

$$\frac{f}{\Delta^{0.7}} \geq 13 \tag{10}$$

The deflection is calculated considering a 1-m wide CLT panel and the frequency is calculated considering static mass only. Therefore the deflection can be calculated using (2 and the frequency using (1.

RESULTS AND DISCUSSION

A preliminary design of Floor 1 and Floor 2 was first conducted as a control. Then by varying the cross sectional stiffness, the support stiffness factor (k_m) and the two-way action provided by CLT the floor vibration response was controlled. The results of the effect of these changes on the analytical methods examined in this paper are discussed with the aim to provide an optimised floor design. The optimisation involves minimising the floor panel mass, while ensuring acceptable vibration performance. The results from the analytical methods of Hamm et al., Mohr and the CLT Handbook provided by FPInnovations are included.

Preliminary Design

The preliminary design of Floor 1 and Floor 2 are simply supported, single span CLT panels with elastic moduli of 10.5 GPa (grade F11). Both floors fundamental frequencies were calculated as below 8 Hz, with accelerations above the allowed limits (

Table 4). Therefore they do not satisfy allowable vibrations, with failure due to low natural frequency with larger than acceptable acceleration. However, both floors passed the unit deflection criterion from the methods Hamm et al. and Mohr (with an acceptability of 40-48% and 10-12% respectively). These two methods are actually relatively similar, the difference being Hamm et al. has more stringent acceptability criteria, omits the check on floor velocity and considers static loads only.

Table 4 Results from analytical comparison and study of varying boundary conditions and material stiffness.

		Hamm et al.		Mohr		CLT Handbook	
		Floor 1	Floor 2	Floor 1	Floor 2	Floor 1	Floor 2
Preliminary design. E=10.5 GPa $K_m = \pi^2$ Floor width = 9 m	Frequency (Hz)	5.4	5.19	4.78	4.6	5.4	5.19
	Unit Deflection (mm)	0.12	0.1	0.12	0.1	0.59	0.63
	Limit Deflection (mm)	0.25	0.25	1	1	**0.29**	**0.27**
	Acceleration (m/s^2)	**0.12**	**0.087**	**0.32**	**0.228**	-	-
	Accel. Limit (m/s^2)	0.05	0.05	0.1	0.1	-	-

It can already be observed from the different analytical methods that while they produce similar values for floor frequency and unit deflection, the limit values, are vastly different and therefore will produce vastly different solutions. The accuracy of the values for floor frequency and damping by analytical methods are supported by comparison with experimental and numerical studies from literature. Studies were conducted at the University of New Brunswick that compared experimental analysis with finite element methods for a floor spanning 5.5 m

(Ussher et al. 2014). For a simply supported CLT floor panel, the 1st modal frequency was found to be 11.4 Hz from experimentation and FEM found a close agreement of 11.1 Hz. Using the analytical methods above, considering a dead load of the slab only, the fundamental frequency was calculated as 10.61 Hz. The study also considered the FE analysis of a CLT panel fully fixed at two ends (but did not carry out test methods); it calculated a fundamental frequency of 20.7 Hz, while analytical methods in this paper produce a value of 24.1 Hz.

Trento University also conducted vibration tests on CLT floors, with modal tests producing a fundamental frequency of 13.31 Hz and a damping ratio of 0.95% for a floor spanning 4.2 m and loaded with steel plates to simulate the non-structural load (Casagrande 2014). The analytical result for the floor assuming a floor damping ratio of 1% was 13.38 Hz, therefore both the frequency and the damping ratio were in close agreement with the experimental results.

Increase the Effective Stiffness EI

Increasing the panel's effective stiffness can be achieved by increasing one or both of the Young's Modulus, E, a material property, or the second moment of inertia (I) a geometric property. By increasing either property, a secondary effect of increasing the mass of the cross section will occur. While increasing EI has a positive effect on both the natural frequency and the acceleration of the floor, increasing the mass has only a positive effect on acceleration and a negative effect on frequency.

While it is generally beneficial to increase the EI of a CLT floor panel, it is important to consider the secondary effects of such an increase, both the positives and the negatives. For example, if the panel was constructed from a hardwood F27 grade timber, the elastic modulus would increase to 18.5 GPa and the density to around 850 kg/m^3, increasing the natural frequency and decreasing the acceleration response. The secondary benefits from such a change are the increase in durability, such as decreased need for preservative application and better performance in a moist environment. There is also a positive effect on the shear slip, known as the "rolling shear', of the CLT panel. An experimental study conducted by Hochreiner et al (2014), found that lower grade timber had a rolling shear failure mechanism, whereas failure was by tensile rupture of individual boards for the higher grade specimens, which led to the higher grade specimens having a better post elastic failure behaviour. The trade-offs, however, are larger craning and transportation requirements, due to the hardwood's increased mass, as well as decreased workability, i.e. fixings and cutting requires more energy.

The elastic modulus for the two floors investigated in this study increased until they were deemed acceptable by the respective analytical methods with results included in Table 5. It was found that each method provided vastly different results, with Floor 1 acceptable at 12 GPa according to Mohr and at 17.9 MPa according to Hamm et al. In either case the results show that the vibration floor design would be acceptable using a F27 timber grade.

Table 5 Results from analytical comparison and study of varying boundary conditions and material stiffness.

	Hamm et al		Mohr		CLT Handbook	
	Floor 1	Floor 2	Floor 1	Floor 2	Floor 1	Floor 2
Minimum E (GPa)	17.9	19.2	12.0	13.0	16.2	17.3
Frequency (Hz)	7.06	7.02	5.11	5.12	7.06	6.66

Increase Support Stiffness

The support stiffness factor (k_m) is dependent on the fixity of the end span connection. For the analytical methods considered in this paper the support stiffness is idealised as either pinned ($k_m = \pi^2$), or fully fixed (k_m = 22.4) (Smith et al 2007). The unit load displacement can also be adapted to account for full fixity, however since the displacement is already within acceptable limits for the simply supported case, the improved behaviour of fully fixed support was not considered. In reality, the floor is unlikely to be either pinned or fully fixed but somewhere in between. By considering the partially fixed properties of a CLT floor panel support connection, the fundamental frequency can be increased without adding more mass to the system.

An experimental study was conducted at the University of New Brunswick into the effect of end support on the vibration performance of CLT floors. It was found that by increasing the number of screws at the support there was a significant effect on the rotational stiffness of the connection (Maldonado & Chui 2014). The study

considered a CLT panel 1 m wide, with spans varying between 2.9 m – 4.5 m and a number of vertical screwed connections (between 1-13) over the 1 m cross section.

The variations in the natural frequency due to the number of screws used for the connection are compared with the Eurocode 5 method for calculating frequency in Figure 5. There are two important observations from the results; firstly that partial fixity causes a significant increase to the natural frequency, approximately 30% for each span tested, and secondly that an increasing span leads to a decrease in differential change, meaning that with increased span there is less effect due to the end support condition[1].

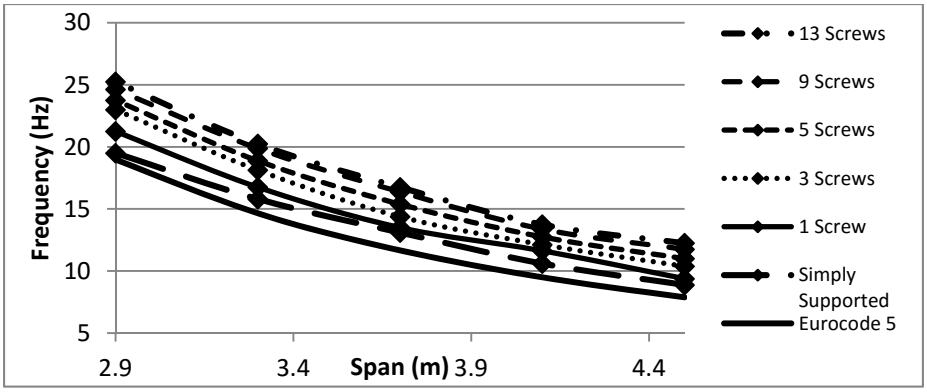

Figure 5 The effect of increasing the number of screw connections on the natural frequency of a CLT floor (Maldonado & Chui 2014). A prediction from Eurocode 5 is included to compare with the test data from the University of New Brunswick.

The results listed in Table 6 show that the analytical methods provide a 5.8% increase in rigidity to satisfy Mohr's criterion whereas a 24.2 % was required by Hamm et al. and 53.7% by the CLT Handbook. The results indicate that partial fixity of supports is a practical option to achieve acceptable levels of vibration with no increase to the modal mass. Results also show that Floor 2 with a lower longitudinal EI requires more fixity to satisfy design limits and therefore this method would be more beneficial for improving the properties of Floor 1.

Table 6 Results from analytical comparison and study of varying boundary conditions and material stiffness.

	Hamm et al.		Mohr		CLT Handbook	
	Floor 1	Floor 2	Floor 1	Floor 2	Floor 1	Floor 2
k_m	12.9	13.4	10.6	11	16.6	17.9
% Fixity	24.20	28.20	5.80	9.02	53.70	64.10
Frequency (Hz)	7.06	7.04	5.13	5.13	9.09	9.41

Two-way action

The final method for increasing the vibration performance of CLT is to consider the two-way action of the material. Timber has traditionally been used as a linear element, whereas the orientation of the boards of CLT renders it with stiffness in both the longitudinal and the transverse direction (Figure 1).

A method of calculating the plate frequency specifically for CLT ((11) and accounting for two-way action has been provided by Thiel (2013). The method considers the effect of a CLT plate supported on 4 sides and requires the value for the longitudinal and the transverse stiffness as well as the twisting stiffness, D^*_{xy}, of the plate.

$$f_{plate} = f_{beam}\sqrt{1 + \frac{2D^*_{xy}}{EI_l}\frac{l^2}{b^2} + \frac{EI_t}{EI_l}\frac{l^4}{b^4}} \tag{11}$$

A method to calculate the twisting stiffness of a CLT plate, is provided in (12 (Silly 2010). This calculation includes a reduction factor, $\kappa_{CLT,P}$, for CLT plates which do not have adhesive between their narrow faces. Since narrow face adhesion is not commonly used in practice the reduction factor is included ((13) where a is the width

[1] Note however, that the study assumed the floor panels were to be supported on CLT walls. For future studies, the effect of supporting the floors on timber LVL or Glulam frames on the vibration performance should be examined.

of the board, t is the thickness of the board and p, q are parameters based on a numerical study and listed in Table 7.

$$D_{xy}^{*} = \kappa_{CLT,P} G_{xy} \frac{t_{CLT}^{3}}{12} \tag{12}$$

$$\kappa_{CLT,P} = \frac{1}{1 + 6p\left(\frac{t}{a}\right)^{q}\left(\frac{t}{a}\right)^{2}} \tag{13}$$

Table 7 Parameters p and q for 3-, 5-, and 7-layer CLT element.

Parameter	3-layer	5-layer	7-layer
p	0.89	0.67	0.55
q	-0.67	-0.74	-0.77

By reducing the width (b) of the original grid layout (9 x 9 m) and accounting for the two-way action of the CLT plates the design limits for each of the analytical methods were satisfied. Table 8 shows that the width of the CLT Floor 1 was reduced from 9 to 3.3 m to satisfy the methods provided by Hamm et al. and from 9 to 7.6 m for Mohr/Richter. The reduction was even more pronounced for the methods by the CLT Handbook, with new floor widths of 2.0 – 2.1 m. The results show that the required reduction in floor width between Floor 1 and Floor 2 are not vastly different. The results from the method by Hamm et al. for example, show a reduction in width of 9 m to 3.3 m for both floors. This indicates that the larger transverse stiffness of Floor 2 is more beneficial for considering the two-way behaviour of CLT rather than the effect of support stiffness or effective stiffness.

The amount of moment transfer between panels is currently unknown. Experimentation on CLT panel-to-panel connections is required to determine the accuracy of these results by calculating the amount of moment transfer between panels.

Table 8 Results from analytical comparison and study of varying boundary conditions and material stiffness.

	Hamm et al.		Mohr		CLT Handbook	
	Floor 1	Floor 2	Floor 1	Floor 2	Floor 1	Floor 2
Floor Grid width (m)	3.3	3.3	7.6	6.4	2.1	2.0
Freq. Increase Factor	1.32	1.37	1.07	1.11	1.68	1.83
Frequency (Hz)	7.13	7.09	5.10	5.10	9.09	9.52

CONCLUSIONS

Analytical methods for calculating the vibration performance of long span cross laminated timber (CLT) floor panels have been compared. The floor panels were considered part of a 9 x 9 m column grid under commercial building loads. Current analytical methods were investigated and compared with finite element analysis and experimental results. The comparison indicated that for single span simply supported beams, there is a general agreement of floor behaviour (natural frequency, velocity and deflection), however, the large difference between limiting values of the analytical methods resulted in vastly different designs.

The methods that were investigated included vibration design calculations from Eurocode 5 and modifications that have been provided by Hamm et al. (2010) and Mohr (1999). The method specifically developed for CLT floors from the CLT Handbook by FPInnovations (2011) was also compared. The modifications provided by Hamm et al. and Mohr provided a method for designing floors with low natural frequencies, between 5-8 Hz, by providing an extra criterion that assesses the floor acceleration. The limit values provided by Hamm et al. resulted in a more conservative floor design than the limit values provided by Mohr. The methods provided by the CLT Handbook generally resulted in the most conservative design.

Floor parameters including the material stiffness, support conditions and two-way plate behaviour were varied to understand the effect on the vibration design. The material stiffness was increased by changing the timber strength grade from F11 up to a F27. The change in material stiffness provided floor designs that satisfied vibration performance. The results indicated that by increasing partial rigidity at the support connections and exploiting the two-way behaviour of CLT plates the floor vibration performance increased to acceptable levels without increasing floor mass.

ABSTRACT

Concrete linings failed before the acceptance of a railway tunnel in a north mountain area of China. A series of experiments were done to analyze the cause of this case. Thaumasite, ettringite, gypsum and calcite were found in the deteriorated concrete linings. The composition of on-situ soil and water samples were also analyzed. Though the sulfate concentration soil behind the linings are not very high, the underground water bring plenty of sulfate after its upsteam flow through a gypsum stratum. It is the external sulfate that induce the deterioration in a low temperature environment which is suitable for thaumasite formation.

KEYWORDS

Concrete lining, damage, thaumasite, external sulphate.

INTRODUCTION

High speed railway construction is booming in China. In mountain area of North China, building tunnel is an economic and effective way for railway engineering. Due to the complicated geological environments, the deterioration of concrete linings in some existing tunnel were reported these years, most of them related to the linkage of groundwater (Huang Bo *et al*.2010). But the failure for a new tunnel due to concrete problems is very rare.

In this paper, a case of an unfinished tunnel lining failure was analyzed. Located in Shanxi province, the construction of the tunnel began in October 2010. The depth of the tunnel is about 300 meters and the temperature in the tunnel always keep at 8-15℃.

In September 2014, some severe deterioration was found in the initial shot-crete lining just before the acceptance of the tunnel. Even the second plain concrete lining was damaged by the expansion, shown in Fig.1

Based on the in-situ test and lab analysis, the cause of the failure was discussed here.

Figure 1 Profile of the tunnel, extruded 2nd lining and surrounding rock water collection

EXPERIMENTAL

Materials

From the primary investigation, it can be deduced that the expansive reaction is the main factor. In order to know what happened to the concrete lining, water, soil, and corrosion products samples were taken from the tunnel site, shown in Fig.2. Since the waterproofing was broken by the expansion, plenty of surrounding water was found in the tunnel. The sediment in drainpipes was also taken to lab.

The grade of shot-crete and 2nd lining is C25 and C30 respectively. Cores were drilled from the shot-crete and second lining to test the compressive strength. The results show that the strength satisfy the design demanding. So the experimental was focused on chemistry analysis.

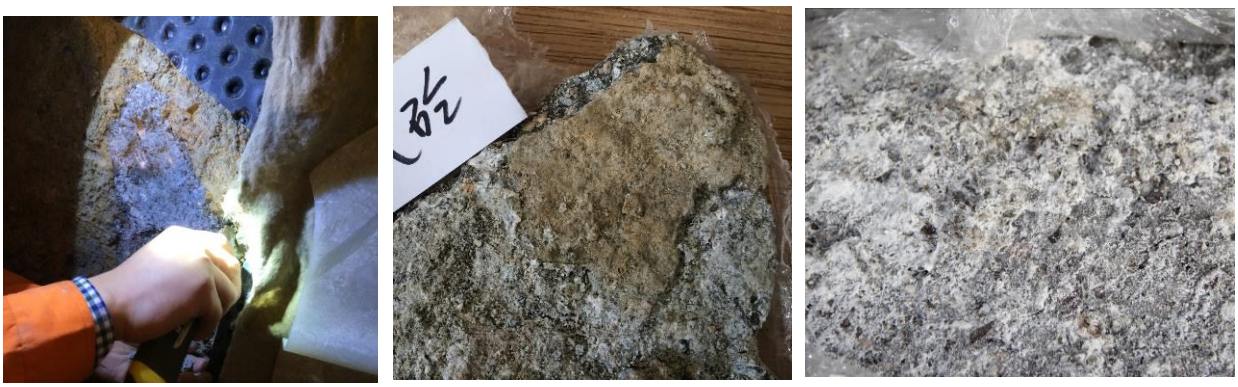

Figure 2 Deteriorated concrete behind the waterproofing board and a white substance on surface

Experimental

The concentration of SO_4^{2-}, HCO_3^-, Cl^-, Ca^{2+}, Mg^{2+} and pH value etc. of water samples was measured according to a Chinese standard "Code of water quality analysis for water conservancy and hydropower development".

X-ray fluorescence (XRF) and X-ray diffraction (XRD) was carried out to analyse the mineral composition and element distribution (S, Ca etc.) of soil, sediment and concrete samples. Then Scanning electron microscope (SEM) and Energy dispersion spectrum (EDS) was used to investigate the morphology of the corrosion products.

Following steps were used to test the SO_4^{2-} concentration in corroded concrete samples:

-Picking out coarse aggregates from the sample, only mortar was left.

-Grounding the mortar and pass the thieve of 80 μm.

-Mix the powder passed 80 μm with 1：1 hydrochloride acid, boiling for about 60 minutes to get solution.

-Measure the SO_4^{2-} concentration by ion chromatography.

-Converting the above value to a concentration of mortar mass.

RESULTS AND DISCUSSION

Adjacent rock water and soil

The results of water analysis are shown in Table 1. It can be seen that the SO42- concentration peak appears in No.5, sample of the adjacent rock water of upstream. According to the geological investigation report, it is the very location where the underground gypsum stratum exist. Following the move of the groundwater, the upstream contacting with the gypsum will have a higher SO_4^{2-} concentration than that of the downstream.

HCO_3^-	99.19	136.39	285.18	198.39	508.37	297.58
tds	536.56	549.9	704.84	821.25	2966.63	937.97
HCO_3^- (mmol/L)	1.63	2.24	4.67	3.25	8.33	4.88

For the surrounding soil of the deteriorated tunnel, the SO42- concentration is not so high, all below 0.5% (mass).

Sediment in drainpipe

Different minerals was found in the sediment in drainpipes including thaumasite, ettringite and gypsum, as shown in Fig. 3, which are products of slufate attack. In normal leakage water, calcite always can be found. XRD and EDS also prove that.

Fig.3 SEM photograph of typical crystal found in sediment

Concrete

XRD, SEM and EDS analysis identified an ettringite/thaumasite mixed crystal as being the main reaction product in the deleterious concrete, similar to the cases reported by Baoguo Ma *et al* （2006）, Crammond *et al* (2003) and H. Justnes *et al* (2006).

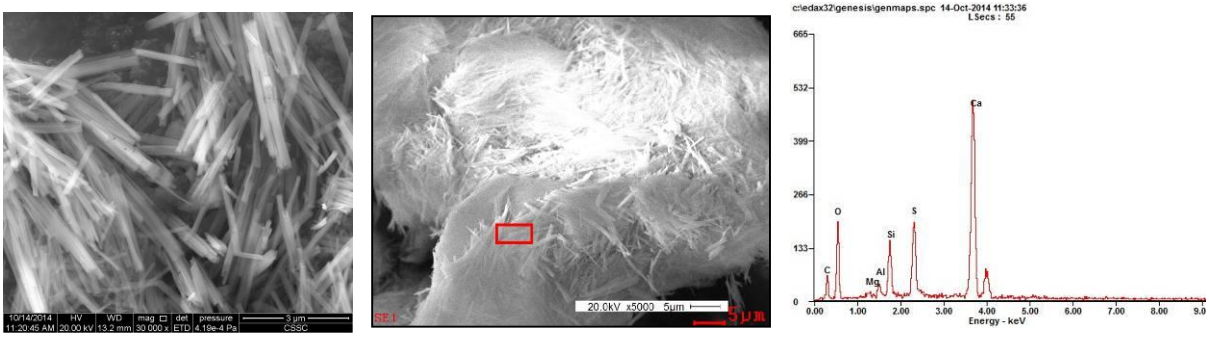

Figure 4 Thaumasite found in deterorated shot-crete

CONCLUSIONS

The main cause of the deterioration of the tunnel lining is the external sulphate attack, resulting strength degradation by thaumasite and expansion by ettringite. Design code of mountain tunnel should be improved to enhance the prevention of deleterious thaumasite formation in the future.

ABSTRACT

A key factor that affects freeze-thaw damages of cement-based porous materials (CBPMs) is the amount of the freezable water confined in the pores that generate large internal pressures during freezing. Taking account of an unfrozen liquid-like layer (ULLL) between ice crystals and pore wall, this paper investigates deformations of a saturated CBPM specimen under freezing with different thickness values of the ULLL. To bridge the macro strains and the local pressure exerted on the pore wall of the material, the thermodynamic equilibrium between the water and ice, and a poroelastic approach were adopted. The hydraulic pressure by volume change as phase transition takes place in the pores, the fusion pressure by energy change as ice forms and penetrates through the thin pores and the hydrothermal pressure by TEC discrepancies between the pore fluids and solid substrate dominate the internal freezing stress. The obtained results reveal that the ULLL plays an important role on the estimation of the amount of ice crystals confined in the pores, and thus influences the pore pressures and deformations of the CBPM specimen used. Appropriate model of the ULLL helps to decrease the deviations between the predicted strains and the experimental data.

KEYWORDS

Freeze-thaw, unfrozen liquid-like layer, pore pressure, poroelasticity.

INTRODUCTION

Frost damage remains the utmost durability problem for cement-based porous materials (CBPMs). Numerous studies have been conducted on the relevant issues (Coussy 2005, Coussy and Monteiro 2008, Dai *et al*. 2013 Scherer 1999, Scherer and Valenza 2005, Wang *et al*. 2014, Sun and Scherer 2010a, Zeng *et al*. 2011,2013a,2014a,b), but more and more experimental and theoretical findings indicated that the mechanical behaviors of CBPMs, together with the chemical--physical process of water solidification confined in the thin pores and the influence factors, need to be advanced.

The material damages relate closely to the mechanical effects arising from the liquid/ice phase change in the porous network. Previous poromechanical studies (Coussy 2005,Coussy and Monteiro 2008, Sun and Scherer 2010a) have linked the internal freezing deformation of a liquid-saturated porous medium to the density change, interface energy, fusion entropy, and thermal expansion coefficient (TEC) discrepancy between pore fluids and solid phases. However, the modeled pore pressures arise easily to 100 MPa at -20 ℃ (Coussy and Monteiro 2008) and the freezing strains can be up to the magnitude of 1% (Coussy 2005, Fabbri *et al*. 2013), which are dramatically larger than the observed data both in-situ and in laboratory. In these poromechanical-based works on the freezing behaviors of CBPMs, the effect of an unfrozen liquid-like layer (ULLL) between ice crystals and pore wall has not been taken into account. Recent experimental and modeling investigations (Zeng *et al*. 2011, 2013a, 2014a,b) have evidenced that the poroelastic model with a ULLL correction can capture the strains of CBPMs saturated with water and/or NaCl solution to a certain degree. However, how and to what extent the thickness of ULLL affecting the freezing behaviors of CBPMs have not been addressed. Motivated by this need, five different models (values) of the thickness of ULLL are adopted in this study. By using the poroelastic approach with the ULLL models, the ice volume distribution (IVD) and water saturation degree of a hardened cement paste (HCP) specimen are estimated. The consequential freezing pressures and strains are analyzed and discussed. The results help to clarify the roles of the ULLL between ice crystals and pore wall to the freezing behaviors of CBPMs.

CONFINED FREEZING

Freezing of water confined in thin space is different with that of bulk water. The premise of ice formation in both manners, however, is that the chemical potential of ice crystals is equal to or lower than that of liquid water. Due to the curvature effect of pores, freezing temperature is depressed because of the lower chemical potential of the confined water. Generally, freezing first takes place in large pores, then penetrate into thinner pores as temperature decreases (Scherer 1999). Triggered by the crystal/liquid interfacial energy (γ_{cl}) and the anisotropic pore geometry (curvature effect), crystallization in confined space generates crystallization pressure (P_A) on the pore wall. Figure 1 exemplifies a case of crystallization pressure building up when ice is entrapped in an anisotropic pore with a large pore chamber connected with small entries. The differences of curvatures of crystal sides (κ_{cl}^s) and crystal caps around pore entries (κ_{cl}^e) generate the crystallization pressure, i.e., $P_A = \gamma_{cl}\left(\kappa_{cl}^e - \kappa_{cl}^s\right)$ (Scherer 1999, Scherer and Valenza 2005). The crystallization pressure is not uniform for an ice crystal. When pore side has a relatively flat curve (point P in Fig. 1), the generated crystallization pressure is relative high. At point N the curvature is negative, crystallization pressure is thus enhanced. Similar cases can be found elsewhere (Dai et al. 2013, Zeng et al. 2014a, Scherer and Valenza 2005).

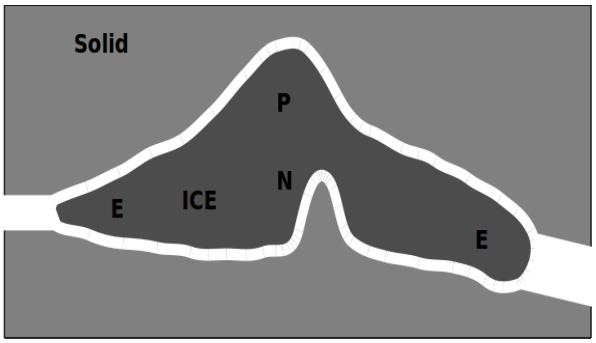

Figure 1 Schematic illustration of an ice crystal in big pore chamber with small entries, see also (Scherer and Valenza 2005, Dai *et al*. 2013, Zeng *et al*. 2014a).

The crystallization pressure, however, remains difficult to be estimated because of the anisotropy and complexity of the pores of CBPM (Zeng *et al*. 2012). Based on the thermodynamic equation for the energy balance at the interfaces of ice crystals and pore water, however, one can easily obtain the pressure difference between ice crystals and liquid water around the ice caps, which gives (Scherer and Valenza 2005):

$$P_c - P_l = P_A + \gamma_{cl}\kappa_{cl}^s = P_{\Delta\rho} + P_f \tag{1}$$

where, P_c is the pressure of ice tips (Pa), P_l the pressure of surrounded liquid phase (Pa), $P_{\Delta\rho}$ and P_f are the pressures induced by respectively density change and energy change when water solidifies: $P_{\Delta\rho} = (V_l / V_c - 1)(P_l - P_e)$ and $P_f = S_f(T_0 - T) + C_f\left[(T - T_0 + T\ln(T_0/T))\right]$ with V_c the molar volume of ice crystal (m^3/mol), V_l the molar volume of liquid phase (m^3/mol), S_f the melting entropy related pressure term at a reference state (Pa/K), C_f the heat capacity change related pressure term as ice forms at current temperature T (Pa/K), R the ideal gas constant (J/mol/K), T_0 the equilibrium bulk freezing/melting temperature (K). Due to the different functions of the energy change, the present energy related pressure term is slightly different with the general internal frost case for pure water saturated CBPMs shown elsewhere (Dai *et al*. 2013, Scherer and Valenza 2005). It is noteworthy that, $P_{\Delta\rho} < 0$ as $P_l > P_e$, because $V_c > V_l$. This indicates that raising liquid pressure tends to melt ice. For the energy related term P_f, $S_f(T_0 - T) >> C_f\left[(T - T_0 + T\ln(T_0/T))\right]$, in many cases, P_f reduces to a simpler expression, $P_f = S_f(T_0 - T)$ with $S_f \approx 1.2$ MPa/K.

UNFROZEN LIQUID-LIKE LAYER

The unfrozen liquid-like layer (ULLL) on the surface of ice has been observed more than 150 years. There are three proposed mechanisms for the formation of this layer: pressure melting, frictional heating, and intrinsic premelting (Dash *et al*. 1995). The thickness of this layer, which is reported to be ranging from one to three molecular layers, depends preliminary on the temperature. The requirement of minimal Helmholtz free energy (or Gibbs free energy instead when the work by pressure is negligible) in equilibrium helps to link the thickness of ULLL to the classic thermodynamic properties of water--ice system (Zeng 2012),

$$\frac{\Delta H(T_0 - T)}{T_0 V_c} = \frac{\Delta\gamma\partial F}{\partial\delta} \tag{2}$$

where ΔH is the fusion enthalpy (J/mol), $\Delta\gamma$ is the surface energy differences as ice premelts (N/m), F is the specific interfacial potential (-). Once the term $\partial F/\partial\delta$ is determined, the relationship between the thickness of ULLL and the temperature can be evaluated specifically. In addition, the choice of $F(\delta)$ depends on the surface force acting between the solid-liquid and the liquid-ice interfaces for ice growing in fine pores (Dash *et al.* 1995). For an exponentially distributing force between the two interfaces, $F=\exp(-2\delta/\varepsilon)$ (Petrov and Furo 2009), the thickness of ULLL can be expressed as,

$$\delta=\frac{-\varepsilon}{2}\ln\left[\frac{-\varepsilon\Delta H(T_0-T)}{2T_0V_c\Delta\gamma}\right] \tag{3}$$

where ε is a parameter that can be determined by experiments. If van der Waals forces were considered, where the repulsive dispersion force between two microscopic bodies is in a limiting separation σ, $F(\delta)=\delta^2/(\delta^2+\sigma^2)$ and $\delta>>\sigma$ was adopted in general case, the thickness of ULLL is then given by

$$\delta=\left[\frac{-\Delta H(T_0-T)}{2T_0V_c\Delta\gamma\sigma^2}\right]^{-1/3} \tag{4}$$

In fact, Eqs. (3) and (4) capture the well-used semi-empirical models for estimating the thickness of ULLL between ice and pore wall,

$$\delta\propto\ln(T_0-T) \tag{5a}$$

$$\delta\propto(T_0-T)^{-1/3} \tag{5b}$$

Generally, Eq. (5a) maybe suitable to describe the thickness of ULLL when ice is exposed to air, whereas Eq.(5b) was argued to capture the thickness of ULLL when ice is in contact with rough solid surface (Dash *et al.* 1995). Furthermore, Eq.(5b) was adopted widely in engineering application, e.g., estimation of pore size distribution (PSD) by differential scanning calorimetry (DSC) with the ULLL correction (Table 1) (Fagerlund 1973). Recent study by Petrov and Furo (2009) suggested that the thickness of ULLL with temperature obeys Eq.(5a) (Table 1), and is much thinner than that used in (Fagerlund 1973).

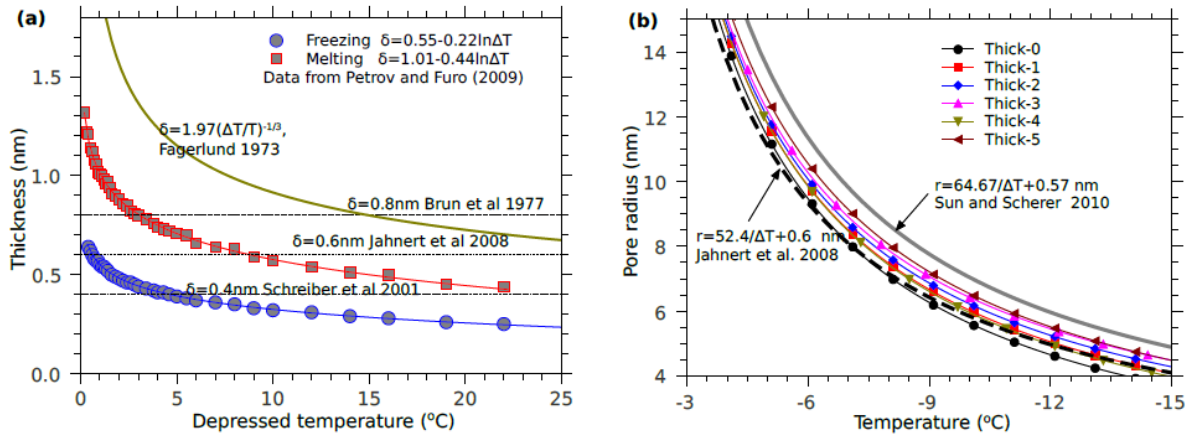

Figure 2 (a), Thickness of unfrozen liquid-like layer between ice and pore wall (Data from (Schreiber *et al*. 2001, Brun *et al*. 1977, Fagerlund 1973, Petrov and Furo 2009, Jahnert *et al*. 2008}), and (b), Gibbs-Thompson relationship corrected by the different ULLL values and those well used in the literature (Sun and Scherer 2010b, Jahnert *et al*. 2008).

Table 1 Thickness of unfrozen liquid-like layer used in the present study

Name	Value (nm)	Method	Ref.
Thick-1	$\delta=0.4$	DSC measurement	Schreiber *et al*. 2001
Thick-2	$\delta=0.6$	DSC measurement	Jahnert *et al*. 2008
Thick-3	$\delta=0.8$	DSC measurement	Brun *et al*. 1977
Thick-4	$\delta=0.55-0.22\ln(\Delta T)$	Theoretical calculation	Petrov and Furo 2009
Thick-4	$\delta=01.97\lvert\Delta T\rvert^{-1/3}$	Theoretical calculation	Fagerlund 1973

Some DSC measurements suggested that the thickness of ULLL is a constant value below 1 nm, e.g., 0.4 nm (Schreiber *et al*. 2001), 0.6 nm (Jahnert *et al*. 2008) and 0.8 nm (Brun *et al*. 1977), see also Table 1. The values and models for the thickness of ULLL mentioned above are also displayed in Figure 2(a) for comparison. The thickness of ULLL by the model of Thick-5, i.e., $\delta=01.97|\Delta T|^{-1/3}$ nm approaches the constant value of Thick-3

(0.6 nm) as $\Delta T = 35$℃. Note that the thickness of ULLL by the model of Thick-4 arrives 0.3 nm when $\Delta T = 10$℃, around one molecular layer of water.

Thermodynamic descriptions of the solid/liquid phase transition in confined geometries predict a shift of the freezing or melting temperature in a function of the pore width, named Gibbs--Thomson equation. For a pure substance in a cylindrical pore of radius R, it gives,

$$\Delta T = \frac{2\gamma_{lc}}{S_f\left(R-\delta\right)} \text{ or } R = \frac{2\gamma_{lc}}{S_f \Delta T} + \delta \tag{6}$$

This expression suggests the presence of a noncrystallized water layer of width δ in coexistence with the confined ice just below depressed temperature ΔT. Figure 2(b) shows the Gibbs-Thomson curves by the different ULLL models. Under a certain subzero temperature, thickening the ULLL tends to enlarge the pore radius. This effect is significant for nano pores (Jahnert *et al*. 2008, Han *et al*. 2012). Figure 2(b) also displays the Gibbs-Thomson curves with different thermodynamic parameters in the literature (Sun and Scherer 2010b, Jahnert *et al*. 2008).

POROELASTICITY

Understanding the physical--chemical process of freezing of water confined in thin pores helps to investigate the pressures building up during freezing, which in turn affects the pores and solid substrates. This, however, remains difficult to associate the local (maybe micro) pressures to macro measurements (e.g., linear or volumetric deformation). Poroelastic analysis can be a good approach to bridge the local phase changes inside pores with the macro deformation of porous material (Coussy 2005, 2010). For simplification, we assume that a porous material is free to expand or shrink ($\Sigma = 0$), the total strain (ε) of the material is thus composed of the terms by internal stresses (pore pressures) and by pure thermal effect,

$$\varepsilon = \frac{1}{3}\frac{b_c P_c + b_l P_l}{K} + \alpha_s\left(T - T_0\right) \tag{7}$$

where K is the bulk modulus of porous material (GPa), α_s the apparent TEC of solid phases (1/℃), b_c the Biot coefficient of ice crystals and b_l the Biot coefficient of liquid water (-). Note that Eq.(7) has minor differences with the expression in (Sun and Scherer 2010a, Wang *et al*. 2014), where the ice pressure P_c was replaced by the crystallization pressure P_A and a pore shape parameter was introduced to interpret the total strain. In this study, the pore shape interpretation was neglected due to the lack of available data.

The deformation of porous skeleton, together with the pore pressures of the phases and TEC discrepancies between the pore fluids and the solid substrate, in turn affects the porosity. This yields,

$$\varphi_{J=cl} = 3b_J\varepsilon + \frac{P_J}{N_{JJ}} - 3\alpha_{\phi J}\left(T - T_0\right) \tag{8}$$

where φ_J is the deviation of the partial porosity occupied by phase J (-), N_{JJ} the Biot's coupling modulus (Pa), $\alpha_{\phi J}$ the coupling TEC of phase J (1/℃). Statistically, a CBPM can be treated as an isotropic material in an appropriate scale. This helps to evaluate the parameters as follows (Coussy 2005,2010),

$$b = 1 - \frac{K}{K_s}, b_{J=c,l} = bs_J, \frac{1}{N_{JJ}} = \frac{b_J - \phi s_J}{K_s}, a_{\phi J} = \alpha_s\left(b_J - \phi_0 s_J\right) \tag{9}$$

where b is the apparent Biot coefficient (-), K_s the bulk modulus of solid matrix (GPa). Under sealed (undrained) freezing condition, the mass conservation of total pore liquid currently contained in the porous materials allows relation of the liquid pressure P_l to the saturation degree s_l and the environmental temperature T, see Refs. (Zeng *et al*. 2013a, 2014a) for more details. Further analysis by considering the local pressure difference between ice crystals and liquid water around the ice caps (Eq.(1)) and the constitutive equation for micro local pore pressure and macro strain (Eq.(7)) finally gives,

$$P = P_{\Delta\rho} + P_{\Delta H} + P_{\Delta\alpha} \tag{10a}$$

$$\varepsilon = \varepsilon_{\Delta\rho} + \varepsilon_{\Delta H} + \varepsilon_{th} \tag{10b}$$

where the subscripts $\Delta\rho$, ΔH and $\Delta\alpha$ denote the effects of density change, enthalpy change and TEC discrepancy between pore fluids and solid matrix. It is noteworthy that, in Eq. (10), ε_{th} not only captures the hydrothermal strain induced by the TEC discrepancies between the pore fluids and the solid substrate, but also that of the pure thermal expansion/contraction of the solid phases as temperature increases/decreases. The detailed expressions for the specific terms in Eq. (10) are displayed in Table 2, where B, P_s, $\mathcal{T}_S$ and $\mathcal{T}_\alpha$ are the coefficients: $B = b_c V_l / V_c + b_l$, $\mathrm{T}_s = \rho_l^0\left(Bb_c / K + s_c\phi_0 / K_c + 1/N_{cc}\right)$, $\mathcal{T}_\alpha = 3\left[\rho_l^0\left(\alpha_s - \alpha_{\phi l} - S_l\alpha_l\right) + \rho_c^0\left(\alpha_s - \alpha_{\phi c} - S_c\alpha_c\right)\right]$ and

$\mathrm{P}_s = \rho_l^0\left(s_l\phi_0 / K_l + Bb_l / K + 1/N_{ll}\right) + \rho_c^0\left[Bb_l / K + \left(s_c\phi_0 / K_c + 1/N_{cc}\right)V_l / V\right]$, with ϕ_0 and ρ_J^0 are the initial porosity (-) and density of phase J ($\mathrm{kg/m^3}$). The detailed derivation of Eq. (10) can be found in (Zeng *et al*. 2013a,2014a).

Table 2 Specific expressions for the terms in Eq.(10)

Pressure	Strain	Note
$P_{\Delta\rho} = -\phi_0\Delta\rho s_c / \mathrm{P}_s$	$\varepsilon_{\Delta\rho} = -B\phi_0\Delta\rho s_c / (3K\mathrm{P}_s)$	Density change
$P_{\Delta H} = \left(b_c / B - \mathrm{T}_s / \mathrm{P}_s\right) / P_f$	$P_{\Delta H} = \left(b_c\mathrm{P}_s - B\mathrm{T}_s\right)P_f / (3K\mathrm{P}_s)$	Enthalpy change
$P_{\Delta\alpha} = -\mathrm{T}_\alpha\left(T - T_0\right) / \mathrm{P}_s$	$\varepsilon_{\Delta\alpha} = \left[\alpha_s - B\mathrm{T}_\alpha / (K\mathrm{P}_s)\right]\left(T - T_0\right)$	Thermal effect

ANALYSIS AND DISCUSION

Ice volume distribution

When evaluating pressures and strains of a CBPM, one should first determine the water saturation degree s_l or ice saturation degree s_c that is directly associated with the thickness of ULLL and PSD. Generally the water saturation degree s_l can be evaluated by experimental measurements, e.g., the DSC measurement for mortars in (Sun and Scherer 2010b), or by indirect method based on PSD of the material determined by other methods, e.g., mercury intrusion porosimetry (MIP) (Fabbri *et al*. 2013, Zeng *et al*. 2014b). In the present study, we employed the indirect method to estimate the IVD and water saturation degree with temperature. The principle of the indirect estimation method relies on the similar physical processes of ice penetration under freezing and mercury intrusion under pressure: a non-wetting phase (ice or mercury) invades pore structure progressively and a complementary wetting phase (pore water or air) retreats correspondingly (Zeng *et al*. 2014b). Figure 3 shows a typical PSD of a hardened cement paste (HCP) specimen (w/c=0.5) (Zeng *et al*. 2014a), where the pores are mainly distributed in the regions of 3--100 nm. For modeling purpose, a multi-peak Gauss formula was used to fit the MIP PSD curve. Excellent agreements between the multi-peak Gauss fitting and experimental data were found in Figure 3.

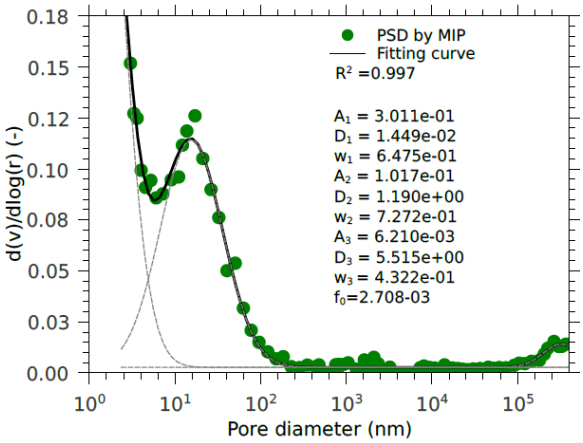

Figure 3 Pore size distribution of a HCP with multi-peak Gauss fitting (Data from Zeng *et al*. 2014a)

Considering the contribution of the ULLL, we established a model to evaluate the IVD and water saturation degree with temperature under thermodynamic equilibrium, see (Zeng *et al*. 2014a,b) for more details. Figure 4 shows the differential and cumulative IVDs with temperature for the HCP specimen with the different ULLL models. The very first differential IVD peaks around 0 ℃ in Figure 4(a) can be observed due to the instantaneous ice formation in big capillary pores. The used temperature step is about 0.1 ℃, so the corresponding instantaneous freezing pore size ranges are estimated as $R > 340$ nm according to the Gibbs-Thomson equation. In such large pores, the effect of ULLL is negligible. As temperature decreases, thinner pores are frozen. The second differential IVD peaks appear around -3.7 ℃ without ULLL correction (Thick-0, $\delta = 0$ nm), and around -3.4℃ with the ULLL model of Thick-5, owning to freezing of water confined in the pores of 15 nm (Figure 3). The ULLL effect is significant. For example, the intensity of the differential IVD peak with the ULLL model of Thick-0 (0.986 μl/g) is significantly higher than that with the ULLL model of Thick-5 (0.720 μl/g). The cumulative IVD values, however, show almost the same numbers (Figure 4(b)) because the volumes of the pores $R > 15$ nm remain minor (0.03 ml/g by MIP). As freezing goes on, water in nano pores solidifies. Different ULLL models lead to different IVD results, at -35℃, the values of cumulative

IVD with the ULLL models of Thick-1, 2, 3, 4, and 5 respectively are 0.107, 0.097, 0.088, 0.114 and 0.085 ml/g (Figure 4(b)), heavily lower than those without ULLL correction and the MIP data.

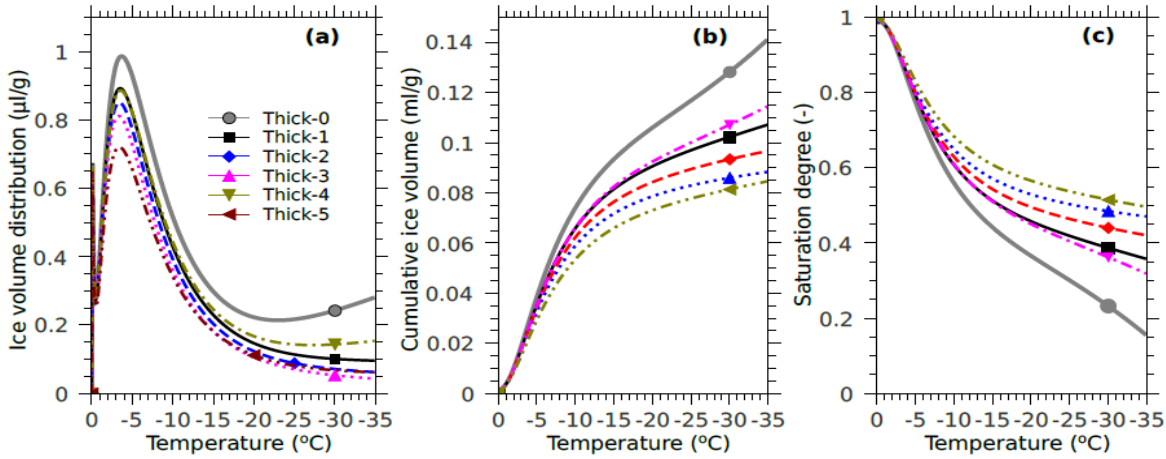

Figure 4 (a) Differential and (b) cumulative ice volume distribution, and (c) water saturation degree versus temperature for the HCP specimen with different ULLL models.

Figure 4(c) displays the water saturation degree s_l upon cooling corrected with the ULLL models. As seen, the values of s_l without ULLL correction always lay below those interpreted with the ULLL models, and thickening the ULLL elevates the s_l values under a subzero temperature. For the non-ULLL case (Thick-0), the entire freezable pores ($R > 1.44$ nm) are occupied by the ice when the temperature decreases to -35 ℃, leaving the water confined in the very tiny gel pores (residual unfrozen volume of 15.6%). When the ULLL is considered, the equilibrium pore radius at -35 ℃ can be changed, e.g., to 1.84, 2.04, 2.24, 1.65 and 2.05 nm for the Thick-1, -2, -3, -4, and -5 models. At the same subzero temperature, consequentially, the unfrozen water occupies more total pores volumes (e.g., around 50% of the total pore volume for the Thick-5 model).

Freezing pressure

Freezing pressures, as decoupled in three different terms in Eq. (10), depend directly on the water/ice saturation degree, temperature and properties of the material and pore fluids. During modeling, we adopted the required parameters of the HCP specimen and pore fluids as follows (Coussy and Monteiro 2008, Zeng *et al*. 2014a,b): $\phi_0 = 0.26$, $K_s = 25.8$ GPa, $K = (1-\phi_0)^2 = 14.1$ GPa, $K_l = 1.8$ GPa, $K_l = 7.8$ GPa, $\alpha_s = 17\times10^{-6}$ 1/K, $\alpha_l = -96\times10^{-6}$ 1/K, $\alpha_c = 52\times10^{-6}$ 1/K. Figure 5(a) shows the pore pressure generated by the density change as ice crystallizes in the pores. The values of pore pressure can be raised up to the magnitude of 100 MPa, consistence with the results reported in (Coussy and Monteiro 2008). However, one should note that in (Coussy and Monteiro 2008) the authors did not consider the effect of ULLL and the lowest freezing temperature was -20 ℃. The values remain significantly lower than those estimated by the classic Clapeyron equation ($P \approx 13.6\times\Delta T \approx 470$ MPa, $\Delta T = 35$ ℃), because we have considered the deformation effects of the porous HCP specimen and pore fluids, see also (Zeng *et al*. 2013). In contrary to the water saturation degree, the values of $P_{\Delta\rho}$ without ULLL correction always lay over those with the ULLL models. In addition, increasing the thickness of ULLL depresses the $P_{\Delta\rho}$ at a subzero temperature. As illustrated in Figure 5(a), at -35 ℃, the values of $P_{\Delta\rho}$ with the ULLL models of Thick-1, 2, 3, 4, and 5 respectively are 138, 117, 103, 152 and 96 MPa, heavily lower than those without ULLL correction (225 MPa). Figure 5(b) displays the curves of $P_{\Delta H}$ that is generated by the energy change of ice formation upon freezing by the different ULLL models. While $P_{\Delta H}$ shows the similar tendency with $P_{\Delta\rho}$, the values of $P_{\Delta H}$ are systematically and dramatically lower than those of $P_{\Delta\rho}$. In addition, $P_{\Delta H}$ almost increases linearly with temperature decreasing for all the ULLL models, because $P_{\Delta H} \propto P_f$ and $P_f \propto \Delta T$ ($P_f \approx 1.2\times\Delta T = 42$ MPa, $\Delta T = 35$ ℃). Again, lowering the thickness of ULLL increases $P_{\Delta H}$, because more heat releases as ice forms in the pores with thinner ULLL.

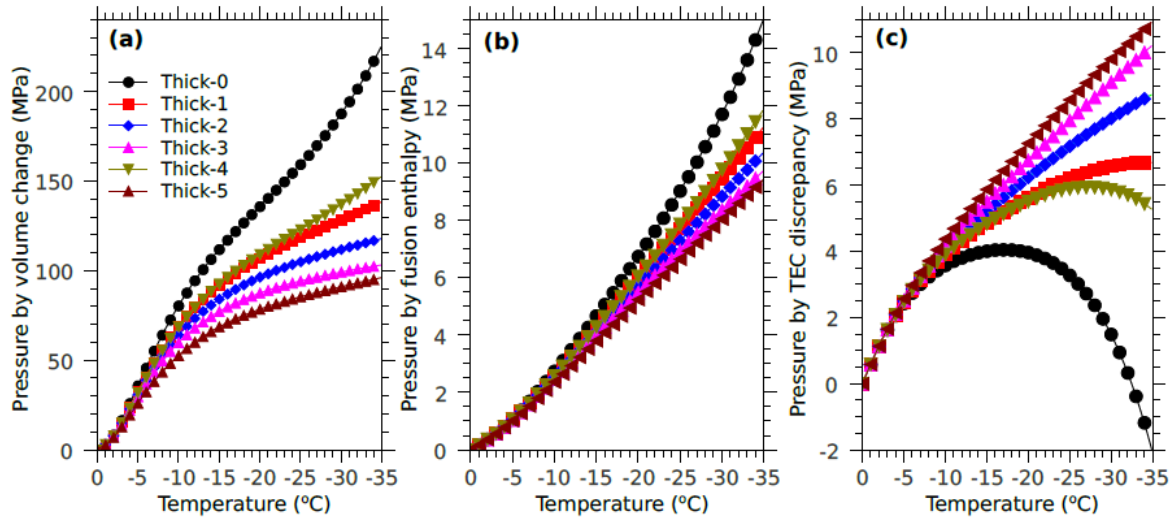

Figure 5 Internal pressures induced by (a) density change, (b) fusion enthalpy, and (c) TEC discrepancy versus temperature for the HCP specimen with different ULLL models

Figure 5(c) presents the curves of hydrothermal stress (or thermal pressure) $P_{\Delta\alpha}$ that is induced by the TEC discrepancies between the pore fluids and solid substrate upon freezing by the different ULLL models. Unlike the values of $P_{\Delta\rho}$ and $P_{\Delta H}$ that increase monotonously with temperature decreasing, the $P_{\Delta\alpha}$ data show completely different ways upon freezing for the different ULLL models. Anomalies of $P_{\Delta\alpha}$ with the ULLL models of Thick-0 and 4 are observed, i.e., $P_{\Delta\alpha}$ increases first to a maximum value then decreases. The increases of $P_{\Delta\alpha}$ with temperature decreasing are originated from the negative TEC of supercooled water ($\alpha_l = -96\times10^{-6}$ 1/K) that expanses as temperature is lowered. Meanwhile both the HCP solid and the ice formed in the pores shrink with temperature decreasing. The synthetic effects of the HCP solid, ice and unfrozen water cause the patterns with which the $P_{\Delta\alpha}$ changes. From the term of $P_{\Delta\alpha}$ shown in Table 2, we find that the sign of $P_{\Delta\alpha}$ depends directly on the thermal pressure coefficient $\mathcal{T}_\alpha$. When $\mathcal{T}_\alpha > 0$, $-\partial P_{\Delta\alpha}/\partial T > 0$, which means that the expansion of the supercooled liquid water dominates the thermal pressure. One the contrary, when $\mathcal{T}_\alpha < 0$, $-\partial P_{\Delta\alpha}/\partial T < 0$, indicating that the contraction of the ice confined in the pores leads the thermal pressure. A critical saturation degree for $\mathcal{T}_\alpha$ emerges as expected. Calculation indicates $P_{\Delta\alpha} = 4.05$ MPa at $T = -17.1$ ℃ and $S_l = 0.407$ for the HCP specimen without ULLL correction, and $P_{\Delta\alpha} = 5.94$ MPa at $T = -27.3$ ℃ and $S_l = 0.385$ for that with the ULLL model of Thick-4, see Figure 5(c). The values of $P_{\Delta\alpha}$ with the ULLL models of Thick-1, 2, 3, and 5 increase monotonously with temperature decreasing because $\mathcal{T}_\alpha$ is always larger than 0.

Freezing strain

Material deformation is an important measurement that inflects the mechanical behaviors of the material under loading and/or internal phase changes. Unlike stress or pore pressure that can be hardly measured directly, deformation or strain of a material can be measured with various methods. Figure 6 shows the strains of the HCP specimen under cooling measured by LVDT, where the detailed measurement method and procedures can be found in (Zeng *et al*. 2014b). It can be seen that the material contracts linearly as the temperature decreases to around -7 ℃ because the pore water remains supercooling. After ice nucleating, the HCP specimen expands instantaneously by about 300 μ (Zeng *et al*. 2014b). As cooling continues, the material expands nonlinearly. The freezing expansions can be roughly captured by the poroelastic analysis, see also (Zeng *et al*. 2014a,b). In Figure 6 are displayed the predicted freezing strains with the different ULLL models. It is noteworthy that the freezing kinetics related to supercooling is still beyond the scope of the poroelastic models, so the pure thermal contraction before ice nucleation and the instantaneous shift of the strain at the nucleation point will not be discussed in this study. It can be seen that the strains of the HCP specimen without ULLL correction are dramatically higher than the measured data. As the thickness of ULLL increases, the predicted strain curve shifts to the lower position in the figure, and captures the experimental data to some extent, e.g., the predicted strain curves with the ULLL models of Thick-2, 3 and 5, see Figure6. For the ULLL models of Thick-1 and 5

that have thickness of 0.4 nm in constant and a logarithm equation decaying with the subzero temperature, the deviation of the predicted strains from the measured data are extended.

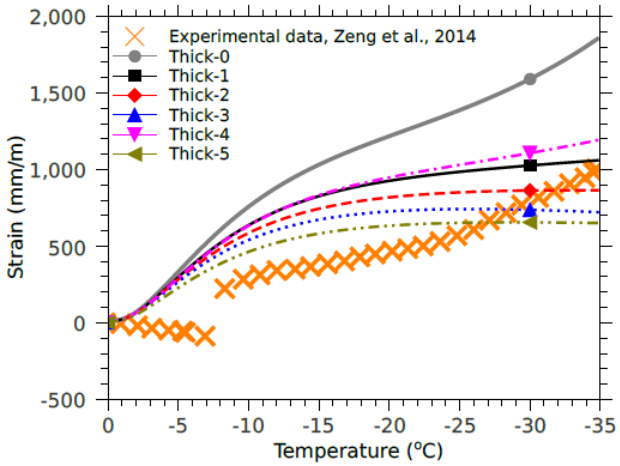

Figure 6 Strains of the HCP specimen under freezing interpreted by different ULLL models and those measured by LVDT (Data from Zeng *et al*. 2014b).

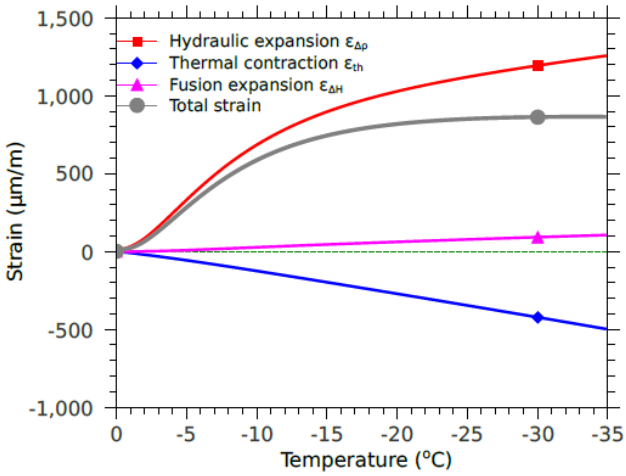

Figure 7 Evolution of the total and specific strains with temperature for the HCP specimen with a constant thickness of ULLL ($\delta = 0.6$ nm)

The origins of the CBPM deformation upon freezing are the effective internal pressure as aforementioned and the pure thermal contraction. More specifically, the total strain of the material is composed of the strains by density change, energy change of water solidification and TEC of the composite system, see Eq. (10). Figure 7 exemplifies the total and the specific strains upon freezing for the HCP specimen with a constant ULLL thickness of 0.6 nm. As seen, the hydraulic expansion $\varepsilon_{\Delta\rho}$, attributed to the hydraulic pressure by the density change as the confined water solidifies, governs the freezing expansion, whereas the fusion expansion $\varepsilon_{\Delta H}$ that is generate from the energy change of ice forming is limited. The thermal strain ε_{th} represents the deformation by pure thermal contraction of the solid paste and that by the hydrothermal stress originated from the TEC discrepancies between the pore fluids and solid substrate as shown in Figure 5(c). While the hydrothermal stress can be as high as 10 MPa, the pure thermal contraction of the HCP specimen remains playing the dominative role on the thermal strain ε_{th}. The coupled effects of the hydrothermal stress and thermal contraction of the solid phases lead to an apparent TEC of 14×10^{-6} 1/K, moderately lower that the TEC of the solid substrate of 17×10^{-6} 1/K.

Note that the matches between the poroelastic models and the experimental data remain coarse, because it has some limitations in the present study that considers an ULLL between pore wall and ice during freezing of which the thickness is constant or changes with temperature. Firstly, we assumed that configurational and vibrational properties of nanoconfined water are the same as those of the bulk. This assumption is challenged by

the disordered structure of ice and water by the actions of confinement. For instance, when the pore size is typically around 3 nm diameter, water freezes to cubic ice, not to the lower energy hexagonal ice, or freezes to a mixture of the two ices with a persistent different structure, thus indicating that crystals and melt coexist. In addition, it have been evidenced that the thermodynamic properties of water vary with both its position in a nanopore and the amount of water in the pore (Han *et al*. 2012, Jelassi *et al*. 2011). Secondly, the properties of pore wall are complex. We assumed a uniform hydrophilic surface for the pores of the CBPM. This assumption maybe too coarse to capture the hydrophilicity of the surfaces of the CBPMs, which are composed of multi hydrates and have extremely complex microstructures (Zeng *et al*. 2012, 2013b). The third limitation of the method used in the present study is the assumption of the cylindrical pores for the cement-based specimens. Porometry measurements by multi methods indicated that pores of CBPMs are much more complex than the simple pores shapes (sphere or cylinder) (Zeng *et al*. 2012). The interactions between the pores wall and water and/or ice molecules, together with the upscaling method (poroelastic approach), provide further research incentives in the future.

CONCLUSIONS

Unfrozen liquid-like layer (ULLL) exists between ice and pore wall due to the mechanisms of pressure melting, frictional heating, and intrinsic premelting. The requirement of minimal Helmholtz free energy with an appropriate specific interfacial potential deduces the well-used semi-empirical models for estimating the thickness of ULLL between the ice crystals and pore wall: $\delta \propto \ln(\Delta T)$ and $\delta \propto (\Delta T)^{-1/3}$.

Five different models for the thickness of ULLL are adopted in this study to interpret the Gibbs-Thomson equation. Analysis results indicate that thickening the ULLL tends to enlarge the equilibrium pore radius under a certain subzero temperature.

Poroelastic model is established to associate the local pore pressure induced by water solidification that takes place in thin pores with the macro material deformation. Both the pore pressure and material strain are composed of the density change, energy change and thermal effect upon freezing.

A typical hardened cement paste (w/c=0.5) with multi-peak pore size distribution is used in the study. The modeling results indicate that the ULLL affects the ice volume distribution and water saturation degree. Without the ULLL correction, it may overestimate the ice volume and underestimate the water saturation degree under a subzero temperature.

Raising the thickness of ULLL tends to lower the pore pressures by density change and energy change as water solidifies, but increase the hydrothermal pressure by TEC discrepancies between pore fluids and solid substrate. Anomalies of hydrothermal pressure emerge for the cases without ULLL correction and with a very thin ULLL attributed to the negative TEC of the supercooled water.

The appropriate ULLL correction mitigates the deviation between the predicted freezing strains and the measured data. More rigorous studies on the interactions between the pores wall and water and/or ice molecules, together with the upscaling method, are required in the future.

ABSTRACT

Under life-cycle service conditions, gas permeability which is usually employed to indicate the durability performance of concrete materials will be changed along with the evolution of microstructure under or after loading. This paper reports an extensive experimental research on the influence of loading condition on the evolution of gas permeability. A cyclic loading scheme under displacement control, which is employed to accelerate the evolution of its microstructure and model the loading condition under real service, is applied on cylinder specimens $\phi 37\times 74$mm dried to constant weight at 60°C. Both axial and lateral strains in the whole loading test are recorded by strain gauge to characterize the change of microstructure macroscopically. At the same time, gas permeability measurement is carried out by a well-designed tri-axial permeater at various loading levels in the planned loading history. The relationship between intrinsic gas permeability, Klinkenberg coefficient and residual strains discussed. It is found that intrinsic gas permeability will become great if the uni-axial loading level is beyond about 70% ultimate strength. Moreover, both the klinkenberg coefficient and intrinsic gas permeability are badly linked with elastic and plastic strains. However, the relationship between the Klinkenberg coefficient and intrinsic gas permeability can be approximated by a semi-empirical law, no matter under or after loading.

Concrete, intrinsic gas permeability, klinkenberg coefficient, residual strain.

INTRODUCTION

The durability of structural concrete is degraded due to the ingression of external aggressive agents such as water, carbon dioxide as well as chloride ion etc. (Cerny 2002). Mass transport properties play the central role in the analysis of durability performance thus the service life (AFGC 2007). Moreover, in some other fields including geotechnical, petroleum, hydrogeology and waste management, the analysis of mass transport in fractured porous materials is of great interest (Reinhardt 1997). Especially, the prediction of waste transport in nuclear waste depository should be paid enough attention due to its significant importance and possible negative influence (Verdier *et al*. 2002). It should be emphasized that, structural concrete material is always subjected to mechanical action, which will make the mass transport properties of porous medium changed greatly due to the possible generation and opening of cracks. The influence of mechanical action or possible cracking should be taken into account when quantitatively predicting the detailed mass transport process.

As a quasi-brittle porous material, structural concrete is vulnerable to micro-cracking under the action of environmental and mechanical actions (Mehta and Monteiro 2006). The ingression of external aggressive agents including liquid, gas and ions will remarkably benefit from this factor. Vast researchers have made great efforts to study the influence of mechanical action on the transport of liquid, gas as well as ion species (Hoseini *et al*. 2009; Zhou *et al*. 2012a, b). To understand the detailed influencing mechanism of mechanical action on mass transport, inert gas permeability is paid more attention due to the possible physical and chemical inter-actions between cracking cementitious materials and liquid with or without interested ions, which may introduce some other factors rather than pure mechanical action (Loosveldt *et al*. 2002). Moreover, in contrast to liquid permeability to water or alcohol, gas permeability is more sensitive to the number, size, orientation, opening as well as connectivity of cracks, which will facilitate the distinguish of even minor influence of cracking from the obvious scatter of concrete materials. Besides, it is also more convenient and less time-consuming to measure gas permeability since inert gas flow can quickly reach stable state even in dense concrete material.

In this paper, the evolution of gas permeability for three structural concrete materials is measured and discussed before, under and after mechanical loading. In Section 2, the preparation of materials and specimen as well as

following experimental procedures are introduced. The measured gas permeability are further given and discussed with respect to stress level and strain level in Section 3 . Finally, the concluding remarks are provided in Section 4.

EXPERIMENTS

Function Materials and specimen

To experimentally investigate the gas permeability of concrete materials under and after loading, three kinds of structural concrete materials C39, C29 and C19 with various water to cement ratios 0.39, 0.29 and 0.19 were prepared with CEM V/A. The mix proportioning of these cement-based materials used in nuclear waste storage application as candidates are detailed in Table 1. Several small beams of size 140×140×560mm were made for each concrete. At the age of 24h, these beams are demoulded and then cured in water until the age of 90 days. After curing, 5 small cylinders of the identical size ϕ37×74mm, whose diameter is about three times of maximum size of gravel, were drilled from small beams. Only the central part of the cored cylinders are cut out to obtain the target cylinder of 74mm height. The two circular end faces of each cylinder is further processed to be flat and parallel to each other to facilitate the later mechanical loading and gas permeability measurement.

Table 1 Mix proportioning and basic properties of three concrete materials

Proportioning	C39	C29	C19
Sand (Limestone, 0-5mm, kg/m^3)	729	809	729
Gravel (Limestone, 5-12mm, kg/m^3)	864	958	864
Cement (CEM V/A, 42.5N, kg/m^3)	393	436	393
Superplasticizer (Glenium 27, kg/m^3)	10.0	11.2	10.0
Water (kg/m^3)	153.8	126.9	75.2
Effective water to cement ratio (-)	0.39	0.29	0.19
Ultimate strength (3 months, MPa)	55	67	71
Maximum axial strain (με)	1850	1780	1870
Capillary porosity (%)	13.2	9.4	7.8
Elastic modulus (GPa)	33.6	43.3	43.4
Poisson's ratio (-)	0.224	0.266	0.259

After preparing 5 cylinders for each concrete materials, 3 of them are tested to obtain their elastic modulus, Poisson's ratio, ultimate strength as well as maximum axial strain. In uni-axial compression, three cycles of compression up to about 30% ultimate strength were first carried out to measure elastic modulus and Poisson's ratio. After that, cylinder specimen are further uni-axially compressed until failure to get ultimate strength and maximum axial strain. The average ultimate strength of concrete material C39, C29 and C19 is 55MPa, 67MPa and 71MPa, respectively. Due to the obvious high water to cement ratio, the strength and elastic modulus for concrete C39 is obviously lower than other two concretes. Moreover, although the water to cement ratio for concrete C29 is larger than C19, there is no remarkable difference about ultimate strength and elastic modulus between them.

Another 2 cylinders were oven-dried to constant mass under constant temperature of 60°C. The mass of each specimen is monitored every 7 days. If the relative difference between two successive measurement are smaller then 0.1%, constant mass is thought to be reached and concrete specimen is totally dried. The capillary porosity is also deduced from the mass difference of saturated and totally dried specimens, as list in Table 2.

Gas permeability measurement

Generally, permeability is understood as a transport properties characterizing the fluid bulk flow within a porous medium under pressure gradient. The flowing velocity q (LT^{-1}) is quantitatively described as follows (Reinhardt 1997),

$$q = -\frac{k}{\eta}\nabla P \tag{1}$$

in which η (Pa·s), P (Pa) and k (m^2) denotes dynamic viscosity, pressure and permeability, respectively. Theoretically, permeability k is independent on the type of penetrating fluid (Reinhardt 1997). However, due to the possible complex physical and chemical interactions between flowing fluid and porous skeleton with high specific surface, the permeability to water, alcohol and inert gas are remarkably different for cementitious materials (Loosveldt *et al*. 2002;Wang *et al*. 2014). Considering from the faced practical difficulty for experimental measurement, permeability to gas is widely adopted to characterize the mass transport properties

thus the durability performance for cementitious materials. It is well-known that gas is a kind of fluid with high compressibility, if ideal gas is assumed, then the apparent gas permeability k_A (m^2) can be calculated by (Scheidegger 1974),

$$k_A = -\frac{Q}{A}\frac{2\eta L P_{atm}}{P_i^2 - P_{atm}^2} \tag{2}$$

Where Q is the volume flow velocity of gas (m^3/s), A is cross-sectional area (m^2), L is thickness of sample (m) and P_i, P_{atm} (Pa) denotes applied inlet and outlet (atmospheric) pressure, respectively. However, the apparent permeability is dependent on the applied pressure due to the gas slippage effect on small pore walls, which is known as "Klinkenberg effect"' (Klinkenberg 1941). Taking slip flow mode and viscous flow mode into account, the actual flow of gas in tight porous media can be quantitatively described as (Klinkenberg 1941),

$$k_A = k_V\left(1+\frac{\beta}{P_m}\right), P_m = \frac{P_i + P_{atm}}{2} \tag{3}$$

in which k_V, β and P_m is the intrinsic gas permeability, Klinkenberg coefficient and average pressure, respectively. Physically, Klinkenberg coefficient β depends on the pore structure of the medium and temperature for a given gas and can be further expressed as (Klinkenberg 1941; Civan 2010)

$$\beta = \frac{c\kappa T}{\sqrt{2}\pi r^3} \tag{4}$$

where r is mean pore radius (m), κ is Boltzmann's constant (J/K), T is temperature (K), c is constant. It is experimentally verified that slippage factor β varies linearly with absolute temperature (Wei *et al*. 1986). Klinkenberg effect is significant with higher coefficient in any situation where the mean free path of gas molecular in porous medium approaches the dimension of pore or micro-cracking. Moreover, β is directly linked to the average pore size in certain sense, i.e., β increases if the mean pore size decreases.

From the above Equation (3), intrinsic gas permeability k_V can be linearly regressed from several apparent permeability k_A, which can be calculated from gas flow velocity under several different inlet pressures P_i. Herein, the gas permeability is tested on totally dried cylinder specimen of size ϕ37×74mm under and after uni-axial loading by steady state method. Thanks to the kind help from Prof. Fredric Skoczylas, a carefully designed permeater highly developed in Ecole Centrale de Lille is adopted, which has been extensively described in references (Davy *et al*. 2007; Benachour *et al*. 2008). Through a tri-axial confining cell providing hydrostatic loading on the circular face of cylindrical samples to keep it air-tight, nitrogen gas is forced to flow within the tested concrete samples under three different inlet pressures while keep the outlet pressure constant as atmosphere pressure. The regulated injection pressure and the corresponding gas flow velocity are continuously monitored every 10 minutes. If the relative difference of gas flow velocity under the same injection pressure is less than 2%, steady state flow is though to be reached. Correspondingly, the apparent permeability can be further evaluated from the steady gas flow velocity and injection pressure through Equation (2). More specifically, in this experimental research work, the hydrostatic pressure is regulated to be almost a constant 3MPa, while the injection pressures are selected as about 10, 15 and 20 Bar. After obtaining the stable velocity under different injection pressure, the apparent permeability thus intrinsic permeability is further evaluated from Equation (3). Actually, it takes about 40 minutes to reach the assumed steady flowing state for each specimen under every injection pressure. Then, one measurement of intrinsic gas permeability and Klinkenberg coefficient costs about 120 minutes.

Uni-axial loading history

To study the gas permeability of concrete materials under and after loading, an axial loading history is carefully designed to apply on each cylinder specimen through the highly developed permeater. Considering the gas permeability of concrete specimen is obviously determined by its pore and cracking structure macro-scopically relating to its strain and displacement, compressive loading is applied uni-axially on the cylinder specimen using Toni Expert machine under displacement control (0.05mm/min) rather than stress control to facilitate the gas permeability testing under the identical compressive state. To ensure the assumed uni-axial compression, the two circular surfaces of each sample is carefully polished to be flat and parallel to each other. For each specimen, the gas permeability is first measured before loading. After that, three cycles with maximum stress of about 30% ultimate strength are applied to eliminate the possible irreversible strain. Then, the specimen is subjected to a cyclic loading history, as shown in Figure 1. First cycle is conducted with the maximum stress about 50% of its strength and keep it constant to allow gas permeability testing under displacement control; then the stress is unloaded to about 5MPa constant to allow gas permeability testing too. 5 more cycles are further carried out with increasing stress ratio about 60%, 70%, 80%, 90% and 95% but constant lower stress about 5MPa. After absolutely unloading, the gas permeability is also measured.

In testing, the axial strain ε_{11} and lateral strain ε_{33} is monitored by 2 strain gauges of length 20mm, respectively. All 4 strain gauges are laid every 90° on the middle portion. The adopted permeater is specially designed to allow uni-axial compression, strain monitoring as well as gas permeability measurement at the same time. Typical stress-strain relationship for specimen C19-1 is shown in Figure 1. Since one measurement of intrinsic gas permeability and Klinkenberg coefficient takes about 120 minutes, the required time to finish the testing for one specimen with 14 measurements of gas permeability is about 28 hours. It costs about 21 work days to finish all the planned experimental testing for all 6 cylinder specimens. The measured axial and lateral strains, deduced intrinsic gas permeability and Klinkenberg coefficients are all listed in the Table 2.

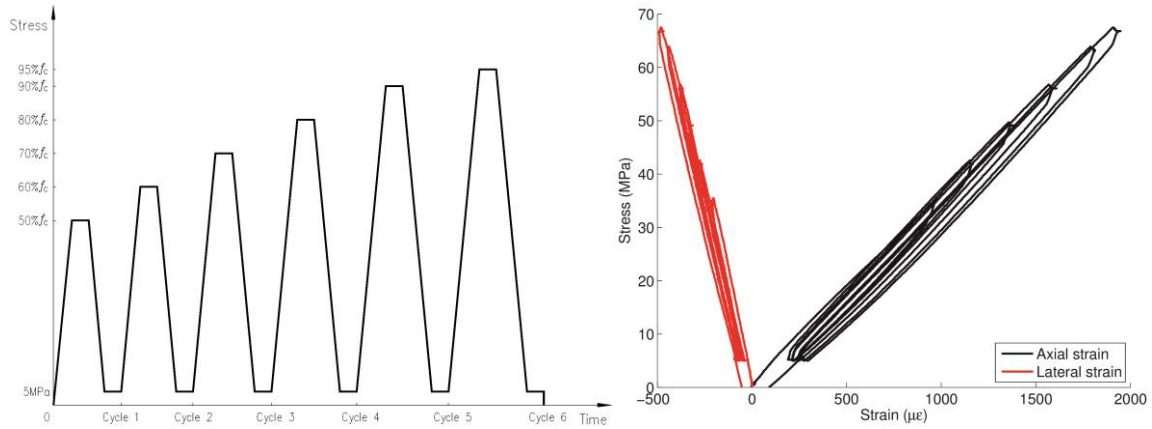

Figure 1 Designed loading history and typical stress-strain curve for specimen C19-1.

EVOLUTION OF GAS PERMEABILITY

Concrete is by nature a quasi-brittle porous material vulnerable to cracking. Generally, micro-cracking will nuclear and develop for material under loading beyond 30\% of ultimate strength. It is the micro-cracking and pore spaces where gas will flow through under pressure gradient. Along with the action of loading beyond the elastic limit, plastic strain will accumulate and the micro-structure of cracking and pores evolve. Furthermore, when damaged concrete material is subjected to loading, the compaction or opening state of micro-cracking and pores will be different from each other, which makes the gas permeability evolve. In another words, the gas permeability of micro-cracked concrete material will be changed with the current loading condition and accumulated plastic strain after loading. Herein, the evolution of gas permeability will be analyzed from these two aspects.

Gas permeability under loading

(1) Intrinsic gas permeability

For the three structural concrete materials concerned herein, the intrinsic gas permeability as well as corresponding Klinkenberg coefficient have been determined from gas permeability testing, which are listed in Table 2. To consistently analyze the relationship between gas permeability and stress / strain ratio for different materials, the relative intrinsic gas permeability k_r and stress ratio σ_r, strain ratio ε_r are introduced and defined as,

$$k_r = k_V^c / k_V^0, \sigma_r = \sigma_c / \sigma_m, \varepsilon_r = \varepsilon_c / \varepsilon_m \quad (5)$$

where k^c_V, σ_c and ε_c is the intrinsic gas permeability under compression, compressive stress and strain, respectively; k^0_V, σ_m and ε_m is the intrinsic gas permeability before loading, maximum stress and strain, respectively. The evolution of intrinsic gas permeability is plotted against the applied axial stress and accumulated strain (including elastic and plastic strains), as shown in Figure 2.

The first observation from Figure 2 is that the relationship between intrinsic permeability and stress, strain is of much scatter. For specimen C19-1, even the first loading level is just 50% of its ultimate strength, the intrinsic gas permeability is obviously larger than the situation before loading, indicating that there are remarkable micro-cracks developed before loading to half of its ultimate strength. When the stress level increases up to about 70% of its ultimate strength, the intrinsic gas permeability tends to be smaller even though more micro-cracks have been introduced by loading. It is easily inferred that there is obvious compaction or consolidation of pores and micro-cracks, which conquer the contribution of newly developed micro-cracks. Beyond 70% of its ultimate strength, the intrinsic gas permeability begins to increase quickly along with the rising of uni-axial loading stress, which attribute to the development of new micro-cracks and their opening.

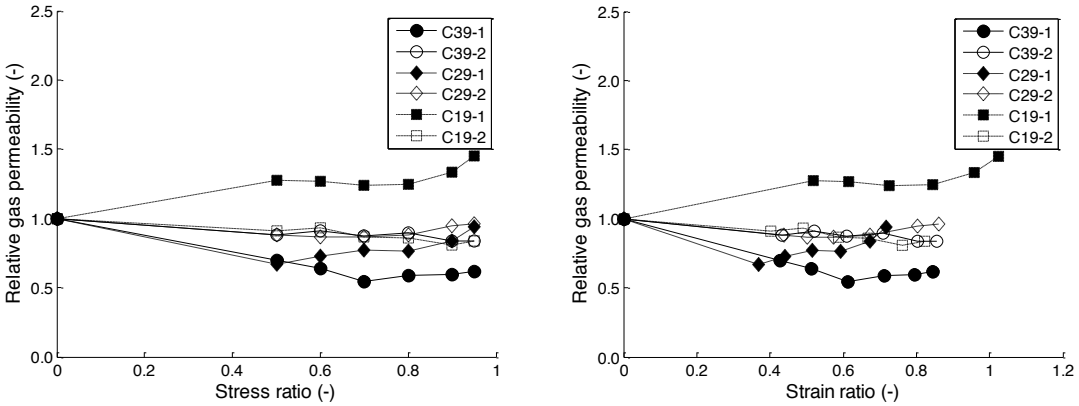

Figure 2 The evolution of relative gas permeability with stress ratio (Left) and strain ratio (Right).

For another specimen C29-1, its intrinsic gas permeability behaviours in a totally different way from specimen C19-1. At the first loading level of 50% ultimate strength, the intrinsic gas permeability is about 30 percent lower than the situation before loading, showing significant compaction and solidation of pores under the loading condition of about 50% of its ultimate strength. Beyond 50% ultimate strength, the intrinsic gas permeability always increases with the rising of loading, indicating the controlling factors of development and opening of micro-cracks.

For the other specimens, their intrinsic gas permeability behaviours in a similar way. When the loading stress is smaller than about 70% ultimate strength, intrinsic gas permeability decreases with respect to loading stress and strain. Moreover, the intrinsic gas permeability becomes larger when loading level is increased beyond 70\% ultimate strength. Except the specimen C39-1, the change of intrinsic gas permeability is relatively small in the range of [-15%, 30%] comparing to the case before loading action. From the above analysis, it can be concluded that the transition point of axial loading stress is about 70% of its ultimate strength, although it may vary.

In terms of loading strain, the intrinsic gas permeability behaviours in a similar way to loading stress. It is emphasized that the transition point of strain ratio beyond which the intrinsic gas permeability begin to increase varies in a wide range from 0.4 to 0.8 of much scatter. From this consideration, it is more reasonable to control the loading stress lower than about 70% ultimate strength to prevent obvious increase of intrinsic gas permeability.

(2) Klinkenberg coefficient

As the Klinkenberg coefficient β is closely linked to the pore/micro-crack size, it is obviously different from each other due to the distinct of their pore / micro-crack size distribution. Similar to the analysis of intrinsic gas permeability, relative Klinkenberg coefficient β_r is also introduced and defined as the ratio of Klinkenberg coefficient under compression β_c to that before loading β_0,

$$\beta_r = \beta_c / \beta_0 \tag{6}$$

To further understand the evolution of micro-structure of concrete material under different uni-axial loading levels, the relationship between relative Klinkenberg coefficient β_r and relative stress / strain ratio σ_r, ε_r is also plotted, as shown in Figure 3.

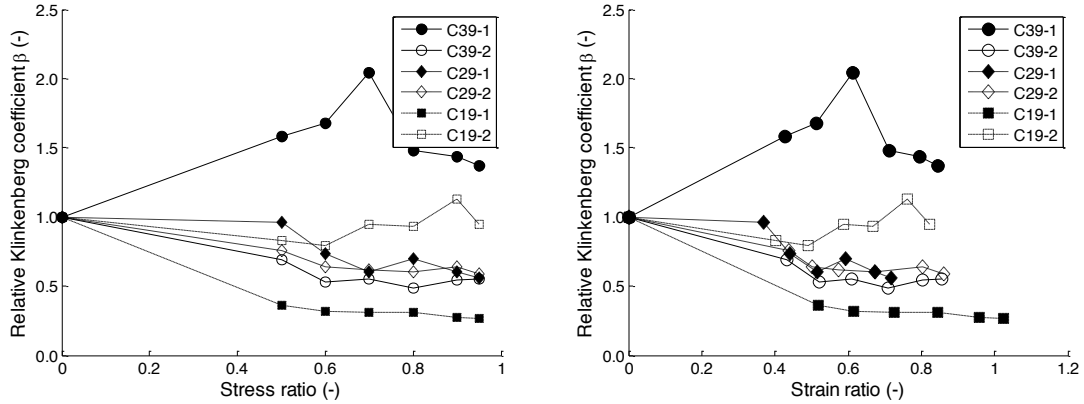

Figure 3 The evolution of relative Klinkenberg coefficient with stress ratio (Left) and strain ratio (Right).

From Figure 3, it is first observed that specimens C39-1, C19-1 and C 19-2 behave in special ways. It is well-known that Klinkenberg coefficient β is closely related to the mean size of pores and micro-cracks in certain sense, and it will increase if the mean size of pores and micro-cracks decreases. From this viewpoint, when concerning specimen C39-1, the mean size of pores and micro-cracks obviously decreases before 70% ultimate strength, which makes the intrinsic gas permeability significantly decreases. Beyond 70% ultimate strength, the mean size of pores and micro-cracks becomes larger with increasing loading stress. Correspondingly, the intrinsic gas permeability becomes larger. For another specimen C19-1, its Klinkenberg coefficient always decreases with respect to rising loading levels, meaning that the mean size of pores and micro-cracks monotonically increase but within a relative small degree. When concerning specimen C19-2, its mean size of pores and micro-cracks first slightly increases but then remarkably decrease if the loading stress is beyond 60% ultimate strength. For the other specimens, the Klinkenberg coefficient first quickly decrease with the rising loading level but then changes in a stable way with small variation. It can be further deduced that the pores and micro-cracks are first compacted obviously within about 60% ultimate strength. After that, the mean size of pores and micro-cracks are almost stable but the number of micro-cracks will be larger and larger, which makes their intrinsic permeability increase. The micro-structure of pores and micro-cracks (mean size, number, connectivity, opening) will be changed in a complex manner with respect to mechanical loading, which determines the evolution of intrinsic gas permeability.

Gas permeability after loading

After uni-axial loading with relative high stress, irreversible plastic strain will accumulate due to the nucleation and opening of micro-cracks. To distinguish the effect of accumulated plastic strain from elastic strain, the relationship between intrinsic gas permeability and plastic strains after loading are further analyzed. Since the lowest compressive stress 5 MPa applied in the loading history is very low, it is neglected and the corresponding strain is approximately thought to be identical to un-loading situation. Moreover, both the residual axial strain ε^r_{11} and volumetric strain $\varepsilon^r_V = \varepsilon^r_{11} + 2\varepsilon^r_{33}$. are analyzed with respect to the relative intrinsic gas permeability and Klinkenberg coefficient.

(1) Intrinsic gas permeability

Figure 4 shows the relationship between intrinsic gas permeability and residual axial / volumetric strains of much scatter. It can be inferred from the first sight that there is no clear relationships between them in terms of either residual axial strain or residual volumetric strain. For specimens C39-1 and C29-1, most of the permeability tested after loading is smaller than that tested before loading, meaning that the contribution of

micro-cracks to the permeability is less than the compaction of pores. For other specimens, the gas permeability is more or less larger than that measured before loading, which is more reasonable due to the micro-cracking or accumulated plastic strain. It is worthy noted that the increase of gas permeability for cracked specimens is limited by the relative high confining pressure (3MPa), which constraints the opening of micro-cracks.

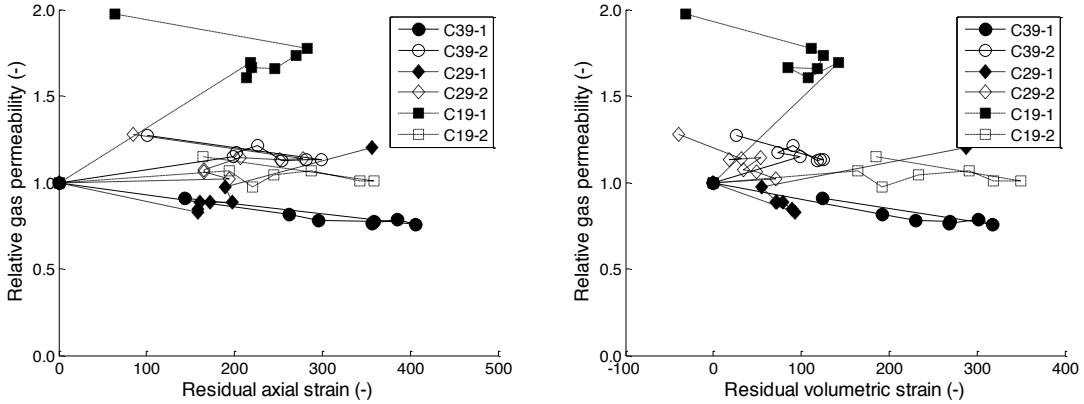

Figure 4 The evolution of relative intrinsic gas permeability with the residual axial strain (Left) and volumetric strain (Right).

(2) Klinkenberg coefficient

The relationships between relative Klinkenberg coefficient β_r and residual axial / volumetric strains are shown in Figure 5. Similar to the relationship between relative intrinsic gas permeability and the residual strains, there are no close links between relative Klinkenberg coefficient and both residual axial strain and relative volumetric strain. Except specimen C39-1, the Klinkenberg coefficient for other micro-cracked specimens are smaller than that measured before loading, indicating that the mean size of pores and micro-cracks are larger than original pores before loading. Since Klinkenberg coefficient represents the mean size of pores and micro-cracks and residual strain indicates the accumulation of micro-cracking, it is easily known from Figure 5 that the cracking pattern for both three structural concrete materials is remarkably complex and heterogeneous from the viewpoint of gas permeability.

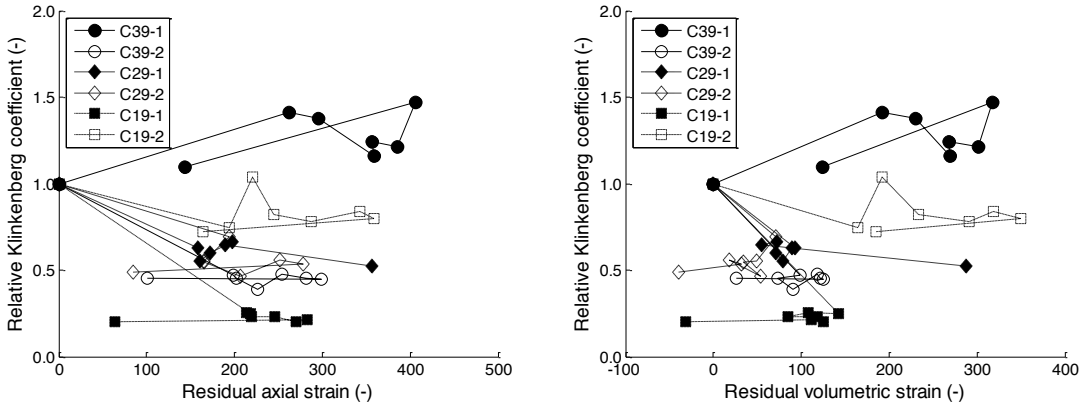

Figure 5 The evolution of relative Klinkenberg coefficient with the residual axial strain (Left) and volumetric strain (Right).

Relationship between gas permeability and Klinkenberg coefficient

Conceptually, both intrinsic gas permeability and Klinkenberg coefficient are determined by pores and micro-cracks of great complexity for concrete materials. Although gas permeability and Klinkenberg coefficient are not well correlated with macroscopic indicator of strains, there might be some links between them. Figure~\ref{fig-Kv-Beta} gives the relationship between intrinsic gas permeability and Klinkenberg coefficient for all situations of under or after loading in the loading history. Except only one points for specimen C19-2, other points follow a certain law. Inspired and borrowed from the suggested model explicitly giving the relationship between intrinsic gas permeability and Klinkenberg coefficient (Tanikawa and Shimamoto 2006;

Civan 2010), the relative Klinkenberg coefficient is approximated by the following formula in terms of relative intrinsic gas permeability as,

$$\beta_r = Bk_r^{-A} \tag{6}$$

in which A and B are constants. Through the least-square method, constant A and B is obtained as 1.60 and 0.65, respectively. And the fitting curve is also shown in Figure 6. It can be seen that this fitting curve can roughly capture the relationship between relative Klinkenberg coefficient and intrinsic gas permeability though the points are scattered.

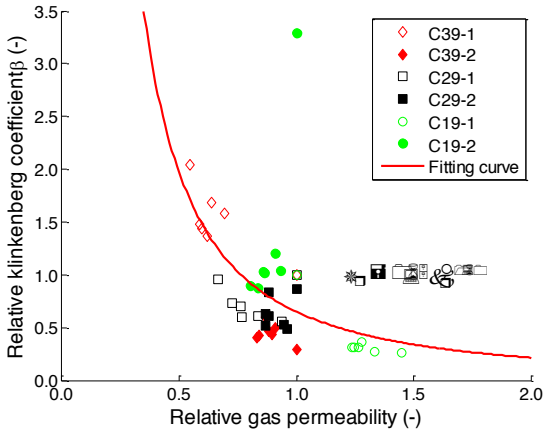

Figure 6 The relationship between relative intrinsic gas permeability and relative Klinkenberg coefficients.

CONCLUDING REMARKS

The evolution of gas permeability for three structural concrete materials are experimentally investigated under and after uni-axial loading. A highly developed permeater, which allows uni-axial loading, gas permeability and strain measurement at the same time, is employed to carry out this experimental research. The intrinsic gas permeability and Klinkenberg coefficient for totally dried cylinders are measured before, under and after a carefully designed loading history. The relationship between intrinsic gas permeability, Klinkenberg coefficient and uni-axial stress, elastic / plastic strains are thoroughly analysed. It is found that the transitional uni-axial stress beyond which the gas permeability begin to rise is about 70% ultimate strength. Under loading condition, the relationship between intrinsic gas permeability and elastic / plastic strains is not clear and much scatter always exist due to complex cracking pattern. In another aspect, the relationship between Klinkenberg coefficient and strains indicates that the mean size of pores and micro-cracks first increase and then keep almost stable under the action of confining pressure. While the number of micro-cracks obviously increases and makes the intrinsic gas permeability increasing. After loading, neither residual axial strain nor residual volumetric strain can characterize the evolution of intrinsic gas permeability and Klinkenberg coefficient. However, the relationship between intrinsic gas permeability and Klinkenberg coefficient can be approximately captured by a semi-empirical law, indicating the implied role of micro-cracks on both intrinsic gas permeability and Klinkenberg coefficient.

ABSTRACT

Reinforced concrete exposed to the marine environment deteriorates more rapidly. Structures constructed at or near the sea shore have to be repaired more often than comparable structures located elsewhere. This study was carried out to develop an understanding of the performance of concrete made up of cements blended by pozzolanic materials. Several mix designs were formulated, incorporating the pozzolans like slag, fly ash and silica fume and calcium nitrate as the corrosion inhibitor. Mix designs were in accordance with ACI 211-1 and pozzolanic materials were added in accordance with ACI 233 and ACI 234. A number of tests were carried out during the study to compare the performance of samples cast from concrete of different mix designs. Tests conducted during the study were Rapid Migration Test (NT Build 492), Half Cell Potential (ASTM C 876), Absorptivity of the oven-dried samples (ASTM C 642), Compressive Strength Test (ASTM C 39) and Flexural Strength Test (ASTM C 293). Results showed that in almost all cases, use of cements blended with pozzolanic materials resulted in an enhanced performance of the concrete. Use of supplementary cementitious materials (SCM) in concrete provides a sustainable and feasible solution to the durability problems in coastal areas. Replacements of OPC by the pozzolan will not only help in conservation of natural resources, but it will also contribute towards reducing pollution and energy.

INTRODUCTION

Deterioration of reinforced concrete (RC) structures has been one of the most extended lessons, taught to mankind. This deterioration is intensely pressing for the structures found on the coast, like Karachi's coastal belt, where structural deficiency caused by leaching is one of the most worrying causes for the engineers. Huge amount of money is being spent annually in rehabilitation and repair of deteriorated RC structures. Construction material, failing to sustain its due performance on the account of environmental aggressions, is dubitably responsible to a large extent. Role of the oceanic aggressive agents become highly undermining in marine environment. The deterioration of RC in marine environment, that may be shore decks, bridges, piles, piers or any other RC structure built in coastal areas, is predominantly because of exposure to sea water. The cost of repairing replacing deteriorated structures has become a major liability for users and different agencies. In US, as highlighted by Gannon et al. (1992), the expenditure was estimated to be more than U.S $20 billion and to be increasing at U.S $500 million per year.

Most of the onshore structures are constructed with normal carbon steel reinforcement due to it being economical compared to stainless steel or galvanic protection alternatives. As concrete bears a natural alkalinity, therefore, under normal condition, it creates a tightly adhering γ-Fe_2O_3 oxide film around the reinforcing steel that keeps it protected as long as this layer is sustained. Before the actual degradation of concrete and the air and moisture access to the reinforcement bars, the corrosion of reinforcement bar is driven up majorly due to carbonation and chloride attack, if present, which Verbeck et al. (1975) described as a unique and specific destroyer. This results in the loss of alkalinity in concrete around the reinforcement bars and also the destruction of passive layer of Fe_2O_3 leading to the initiation of actual corrosion. The volume of iron oxidation product, eventually, causes severe cracks in the concrete providing unavoidable path for oxygen and water, bridging the structure over the threshold of corrosion.

For most of the structures exposed to marine environment, however, the major extent of chlorides in concrete originates from the external sources. The penetration of this chloride occurs through various transport mechanisms depending upon the exposure conditions. Chloride ions can also be a great predator for a structure that is not at or near the coast. It can originate with different variety of reasons. In some countries, even deicing

salts, used to combat the build-up of snow and ice on transport infrastructures, are the greatest source of chloride (Cement Concrete & Aggregates Australia, 2009). Point to be noted here is that, in the case seawater exposure particularly, the chloride poses a much, in fact the sole, threat to steel in concrete than sulfate do to concrete as calcium sulpho-aluminate or ettringite (the expansive product of sulfate and tri-calcium aluminate in the cement) is more soluble in the presence of chloride and hence it does not initiate a considerable disruptive expansion.

Since the relationship between the durability and the strength remains unsettled, the durability of concrete is subordinated with numerous factors and measures. A significant function for durability indexes is the water to cement ratio, lesser the pores, denser the microstructure, lesser penetration of water and ionic aggression and in turns lesser chance of deterioration. Another renowned way of mitigating the degradation of concrete, under the attack of ions, is the replacement of OPC by supplementary cementitious material as explained by Philip et al. (2007), slag (ground granulated blast-furnace slag), silica fume and fly ash. These fine particles of pozzolans help in densely packing up the pores leading to permeation and also give rise to formation of excess ultra-stable calcium-silicate-hydrate (C-S-H) through pozzolanic reaction.

Corrosion inhibitors like calcium nitrate can be used in reinforced concrete which does not actually stop corrosion, but delays its initiation. Calcium nitrate in concrete oxidizes the part of the passive layer of ferrous oxide (+2 oxidation state) into ferric oxide (+3 oxidation state). This ferric state is stable to chloride as compared to ferrous state and keeps the steel passive. This anodic effect on steel reinforcement bars protects it from the degradation by chloride attack. Air-entrainer reduces the probability of segregation and bleeding, ensuring a uniform paste of concrete and improving durability. The microscopic air bubbles can act as a barrier for the water and also provide chemical resistance. External waterproofing membrane can also be used to hinder the penetration and absorption of water to a great extent. Membrane system can be categorized as asphalt-impregnated fabric, cementitious, polymer, elastomeric and asphalt-laminated. The initiation of corrosion of steel reinforcement can also be delayed by coating the reinforcement bar with the referenced anodic zinc. Zinc has more electronegative potential than steel that means it is more sensitive to corrosion. Zinc puts steel in the cathodic state, and it being anodic, exposes itself to the oxidation rather than the steel.

This research is aimed to study the performance of reinforced concrete, made up with different proportions of pozzolans in the mixes along with calcium nitrate dosing and external waterproofing applications, exposed to marine environment. Performance of different mix designs was determined by using several performances related tests available in the literature. Tests conducted during the study were Rapid Migration Test (NT Build 492), Half Cell Potential (ASTM C 876), Absorptivity of the oven-dried samples (ASTM C 642), Compressive Strength Test (ASTM C 39) and Flexural Strength Test (ASTM C 293). Results showed that in almost all cases, use of cements blended with pozzolanic materials resulted in an enhanced performance of the concrete exposed to marine environment.

EXPERIMENTAL PROGRAMME

Mix Designs

Nine different mix designs were used in the study in order to fulfill the scope of studying the performance of marine concrete enhanced by the addition of pozzolans like fly ash, silica fume and slag, along with the use of corrosion inhibitor (calcium nitrate). Details of mix designs are shown in Table 1. The water to cement ratio was kept fixed as 0.4. Proportions of the ingredients were designed as per ACI 211.1, except for mix design A. Mix design A contains the ingredients in 1:2:4 ratio (M15 nominal design), and serves as control mix design as it represents general practice in local construction industry for the construction of general residential buildings. Optimum 4% dosage of calcium nitrate was added in a mix design. Moreover, for workability and ensuring proper compaction with w/c ratio of 0.4, high-range water reducing plasticizer as well as water reducer and retarder was used. For each mix design 0.2 cubic yard concrete was prepared. Minimum cover of 3″ was maintained for the reinforcement as per specification of ACI 357.

Supplementary cementitious materials used in the study as a replacement of Portland cement in concrete were locally available slag cement containing 30 % slag, Fly ash (Class-C) with the activity index up to 88.72 %, and silica fume from BASF Chemicals & Polymers, MasterLife SF 100. Low water to cement ratio, aimed to make concrete denser and more impermeable, was achieved by the help of High-Range Water Reducer (Type-F) from BASF Chemicals & Polymers, MasterPozzolith LD10 and Super Plasticizer was used additionally for easing the workability as proposed by Plante et al. (1986). Maximum size of coarse aggregate used was ¾ inch, sand passing #4 sieve was used as fine aggregate. Air entrainer (MasterAir 720) and waterproofing membrane (MasterSeal 550) from BASF Chemicals & Polymers, were also used in the study.

Table 1 Mix Designs

Mix Design	A	B	C	D	E	F	G	H	I

Compressive and Flexural Strength

Strength has always been the most important characteristic of concrete along with durability. Reduction in compressive and flexural strengths of all mix designs used in the study was determined by exposing respective specimens to marine environment for 100 days after 28 days of curing in normal conditions. An actual splash zone near the construction site of a Quay wall at the harbor port, by China Harbor Engineering Company Group, was selected as marine environment and strength reduction was determined after 100 days. Concentration of different ions in the marine water samples from different locations of Karachi beach is shown in Table 2. China harbor port was selected due to the severity of marine environment.

Table 2 Ionic Concentrations present in different Sea Water Samples

Ions	Clifton Creek	China Harbor Port	Clifton Sea View
Sulfate	18.95 gm/10 ltr	27.7 gm/10 ltr	22.3 gm/10 ltr
Sodium	81.97 gm/10 ltr	91.96 gm/10 ltr	78.97 gm/10 ltr
Potassium	12.21 gm/10 ltr	11.65 gm/10 ltr	10.59 gm/10 ltr
Calcium	5 gm/10 ltr	12 gm/10 ltr	6 gm/10 ltr
Magnesium	15.79 gm/10 ltr	15.32 gm/10 ltr	14.39 gm/10 ltr
Chloride	229.92 gm/10 ltr	254.92 gm/10 ltr	222.43 gm/10 ltr

Compressive strength was determined by testing 6 inch diameter cylinders in accordance with ASTM C 39, while flexural strength was determined by testing 24 inch long beams with 6 inch square cross-section subjected to three-point bending, in accordance with ASTM C 293. Three (03) samples of each type were cast for testing. A set of samples was maintained in controlled non-aggressive environment, a set was coated with waterproofing membrane layer for exposure in marine environment while a set of sample were exposed to the marine environment without water proofing membrane.

Chloride Penetration (R.M.T)

Chloride induced corrosion in marine reinforced structures is a key mechanism directly affecting the durability of the structure. Thus, it can be used as an effective quantifiable durability index of concrete. Long term tests such as the Salt Ponding Test (AASHTO-T259) and Bulk Diffusion Test (NT Build-443) provides a better estimate of chloride penetration, but they consume a considerable amount of time. On a fast track, Rapid Chloride

Penetration Test (RCPT) (ASTM C-1202 and AASHTO T-277) is commonly utilized. The test is widely criticized for its flaws and the incorrect correlation with the long term Salt Ponding Test. Due to flaws in RCPT, electrically-accelerated chloride penetration testing method, known as Rapid Migration Test (RMT) or Rapid Chloride Migration Test (RCMT), was used in the present study, which quantify the ingression of chloride ions. This test was standardized in 1999 by Nordic Council Of Ministers as NT Build 492 (1999).

Specimen of 2 inches thickness and 4 inches diameter were prepared by slicing the 4 inches by 8 inches cylinder at their mid-height. A water-cooled diamond saw was used for this purpose. After desiccation and treatment, the specimen was fixed in a rubber sleeve with the help of a pair of stainless steel clamps that should ensure the impermeation of both NaCl and NaOH solutions to the either sides as shown in Figure 1. The stainless steel wire meshes were placed into the electrolytic solutions near the both sides of the specimen. The steel mesh inserted in NaCl solution was made cathode by connecting it with the negative terminal of the supply and the mesh in NaOH solution was made anode by connecting it with the positive terminal of the dc power supply. With the frequent monitoring of the current supplied, 60 Volts potential difference was applied across the specimen for 18 hours. After which, the specimen was axially split. Adopting the calorimetric method, the silver nitrate solution (0.1N) was immediately sprayed onto the exposed surface. The chloride ion presence was indicated by white silver precipitation separated by a brownish color of chloride absence. The average depth of the chloride penetration was noted for further calculation of Chloride-ion Migration Coefficient or Non-Steady State Migration Coefficient (D_{nssm}).

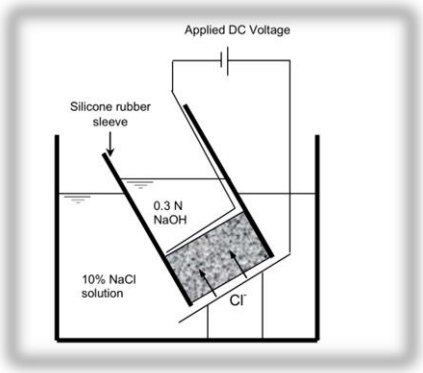

Figure 1 Schematic diagram of Rapid Migration Test Setup

Absorption Capacity Test

Absorptivity of samples cast from all the mix designs was determined in accordance with ASTM C642. Specimens were extracted from 4 inches diameter cylindrical samples by slicing them with the help of a water cooled diamond saw. Two (02) inches thick slices were obtained for the test.

Absorption of oven dried sample after immersion was evaluated as per specifications of ASTM C642. Specimens were oven dried for 24 hours at the temperature 85°C until the mass became constant and weighed. This weight was noted as the dry weight (W1) of the cylinder. After that the specimen was submerged in water at 85°C for 24 hours. Then this weight was noted as the wet weight (W2) of the cylinder. The water absorbed is simply represented in percentage of the sample's dry weight and calculated by Eq. 1 stated below.

$$\%\ \text{water absorption} = \frac{(W2 - W1)}{W1} \times 100 \quad (1)$$

Where,

W1 = Oven dry weight of sample;
W2 = Wet weight of sample after it reaches a constant weight.

Corrosion Rate Test

The corrosion potential was measured by the help of copper/copper sulfate electrode. The setup was prepared in accordance with the specifications of ASTM C-876. The half-cell setup simply consisted of a container porous at the bottom consisted of the copper rod, not in physical contact with the container, filled with a saturated copper sulfate solution. A lead wire connected the copper rod to the high impedance voltmeter and also a connection is made to the exposed steel reinforcement of the specimen. The specimens were subjected to a chlorine environment of 5% NaCl solution. The corrosion potential readings were obtained weekly. The corrosion activity is evaluated in accordance with ASTM C-876. Evaluation criteria suggested by ASTM C876 when Copper/Copper Sulfate electrode is utilized is as follows:

1. If potentials over an area are greater than -0.20 volt, there is a probability greater than 90 percent that no steel corrosion is occurring in the area at the time of measurement.
2. If potentials are in the range of -0.20 to -0.35 volt, corrosion activity of the steel in the area is uncertain
3. If potentials are less than -0.35 volt, there is a probability greater than 90 percent that steel corrosion is occurring in the area at the time of measurement.

RESULTS AND DISCUSSION

Compressive and Flexural Strength

The targeted ultimate compressive strength for the mix designs was 5000 psi. This was achieved by most of the mix designs except mix designs E, F and G as can be seen Figure 2. In general, all the mineral additives added advantage in the strength, except for fly ash, which caused considerable drop in strength whether it is used separately or in combination with silica fume and slag. This may be attributed to quality of fly ash used in the study, and more experimentations and testing may be needed to account for this drawback. Replacement of cement with silica fume in mix designs B and C and blast furnace slag in mix design D resulted in enhanced strength of concrete. Addition of calcium nitrate in mix design I seems to have no effect on strength and strengths achieved by mix designs H and I are almost similar to control mix design. All the samples showed reduction in compressive strength after exposure of 100 days to marine environment with mix designs B, C and D performing better than rest of the mix designs followed by mix designs A, H and I. Mix design G with all the three pozzolans depicted highest strength loss in marine environment.

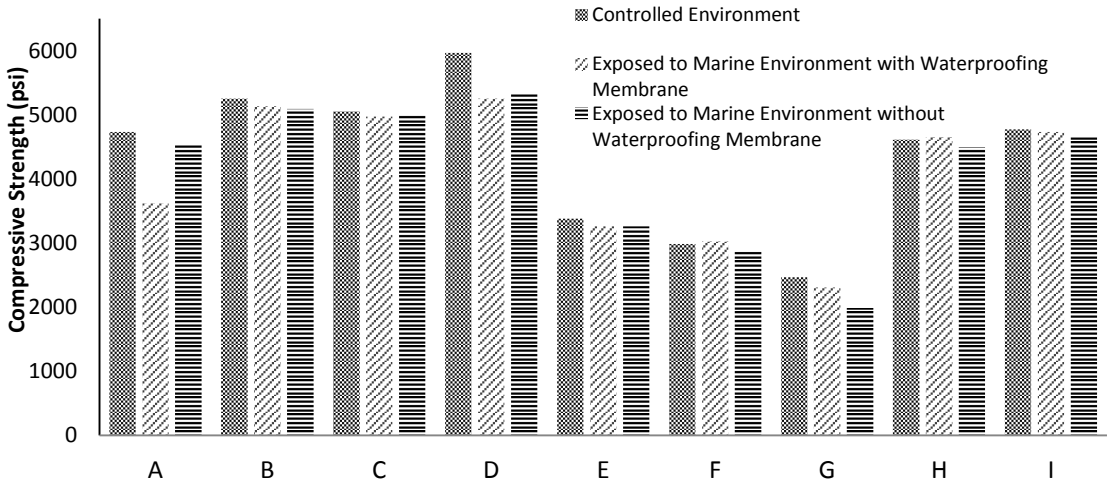

Figure 1 Compressive Strength Results of Different Mix Designs

Results for flexural strength are shown in Figure 3. A trend similar to compressive strength can be seen in Figure 3 that silica fume and slag attributed to the increase in strength while fly ash influenced a considerable loss in flexural strength as well. It is mentionable that the mix containing 30% slag showed highest value of strength and least strength degradation in marine exposure.

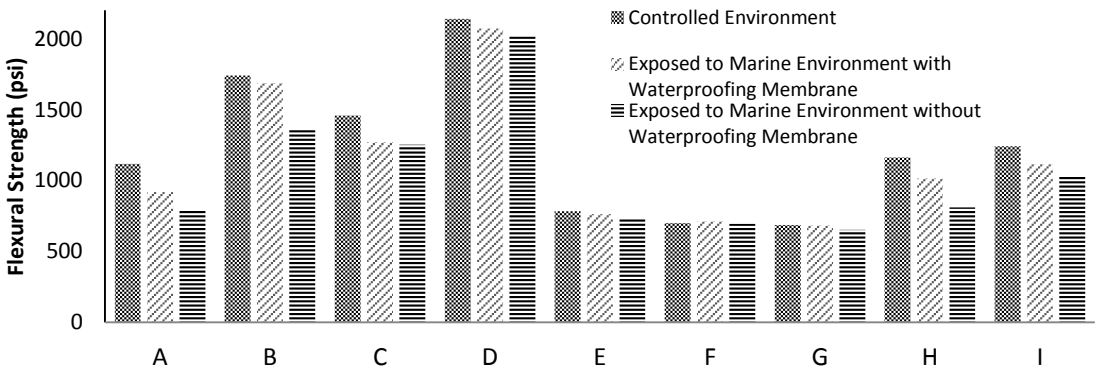

Figure 2 Flexural Strength Results of Different Mix Designs

Chloride Penetration (R.M.T)

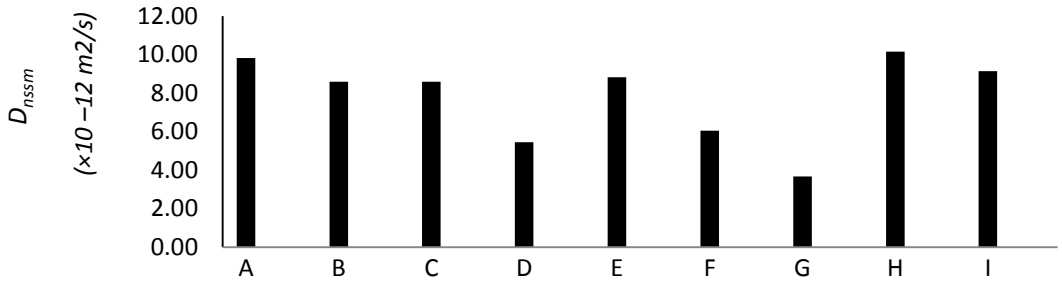
The test was performed for Chloride-ion Diffusion Coefficient or Non-Steady State Migration Coefficient according to the specifications provided by NT Build 492. The diffusion coefficient was also calculated accordingly. The average temperature of the anolyte solution was 30°C throughout the tests. 60 volts current was supplied for 18 hours. The depth of chloride penetration indicated by silver nitrate solution was considered as mean chloride depth for each sample.

NT Build 492 offers a simplified formula for the Non-Steady State Migration Coefficient (D_{nssm}) defined in Eq 2.

$$D_{nssm} = \frac{0.0239(273+T)L}{(U-2)t}\left(x_d - 0.0238\sqrt{\frac{(273+T)Lx_d}{(U-2)}}\right) \quad (2)$$

Where;

D_{nssm}: Non-steady state migration coefficient, $\times 10^{-12}$ m^2/s;
U: absolute value of the applied voltage, V
T: average value of the initial and final temperature in the anolyte solution, C
L: thickness of the specimen, mm
x_d: average value of the penetration depths, mm
t: test duration, hour



dnssm	(×10 –12 m2/s)	9.8	8.6	8.6	5.4	8.8	6.0	3.6	10.	9.1

Figure 3 Chloride Rapid Migration Coefficient Results for Different Mix Designs

Chloride-ion migration test results of different mix designs are compared in Figure 3. The fact that diffusion coefficient of the same mix design did not differ by a wide scale; in a way justify the authenticity and reliability of the results. The slag cement mixes G and D, showed a much lower value of diffusion coefficient, than the mixes containing just OPC denoted as A, H and I. Fly ash and silica fume also contributed to the reduction in the diffusion coefficient's value for B, C, D, E and F mix designs. Additionally, the mix with fly ash and silica fume both in mix design F and incorporating slag along with them in G, performed best against chloride ingression and showed least chloride penetration depth as well. Dosage of calcium nitrate did not seem to offer any mentionable resistance against chloride ions induced with a potential difference.

Absorption Capacity Test

Absorption capacity of mix designs is shown in Figure 5. Percentage of water absorption of dry specimens by weight as per ASTM C-642 of all the mix designs is compared in Figure 5. Mix Design E shows higher water absorption as compared to the other mix designs. Silica fume on the other hand proved to be an effective means of reducing absorptivity, despite its small portion replacement of cement (8% to 10%). Slag, that is effective when it replaces the cement in a large proportion, also showed a considerable decrease in absorptivity. Fly ash used in combination with Silica Fume shows a reasonable lower absorptivity as compared to the Fly Ash used alone. Calcium Nitrate did not seem to affect the absorption property of concrete.

Corrosion Rate Test

The half-cell potential was noted with the half-cell submerged setup, developed in accordance to ASTM C876. The corrosion potential of steel embedded in concrete, exposed to a chloride aggressive environment of 5% NaCl for a period of 35 days, showed the mutually comparable rate of corrosion of steel in reinforced concrete due to salt attack, presented in Figure 6. It is clearly visible that the corrosion potential, that represents the corrosion activity in concrete specimen, decreased adequately with the use of pozzolans. Slag and fly ash reduced the

potential by a wider margin. Silica fume did seem to be very effective for this perimeter. Corrosion inhibitor used, which was calcium nitrate, helped in delaying the corrosion process, a great deal. A significant low corrosion activity was witnessed in the concrete samples containing calcium nitrate. The graph depicts the significance and future scope of corrosion inhibitors.

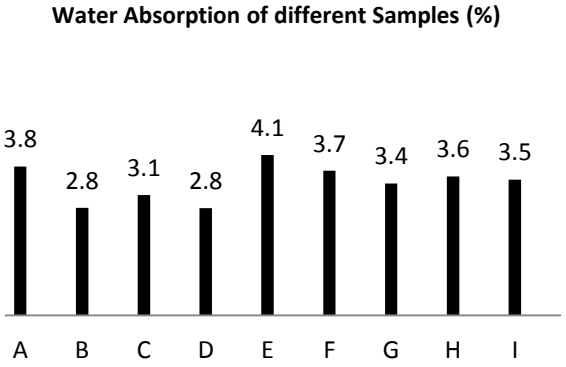


Figure 5 Absorptivity for Different Mix Design

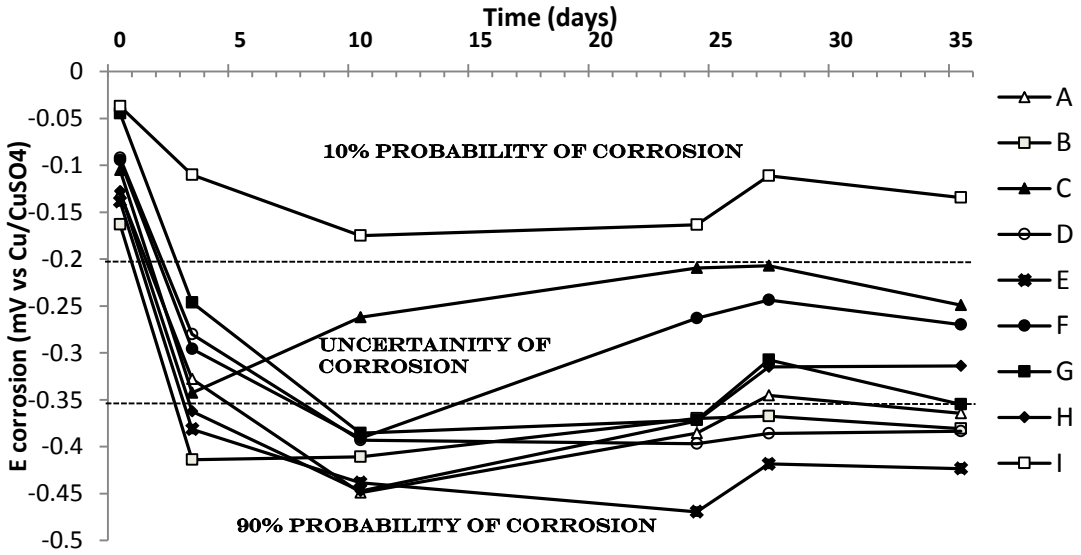

Figure 4 Variation of Half-Cell Corrosion Potential of Reinforcement versus Time of exposure to Chloride Attack (5% NaCl)

CONCLUSIONS

Following conclusions can be drawn from the study:

1. Performance of all the mix designs in terms of strength gain were better or comparable to control mix design except for mix designs E, F and G where fly ash was used separately or with silica fume and slag. This may be attributed to slow strength gain of fly ash which also affected the performance of silica fume and slag.
2. Resistance to chloride migration was best observed for the mix design G followed by D and F indicating that slag only or combination of slag, silica fume and fly ash can produce dense, impermeable and durable concrete.
3. Least absorption capacity was observed for the mix designs B and D followed by C and G reflecting better performance of Slag and silica fume as compared to fly ash which again shows highest absorption capacity which is even higher than the control mix design A.

4. Performance of mix design I, with calcium nitrate as corrosion inhibiter, was the best in Half Cell corrosion rate measurements followed by mix designs C, F, H and G. Performance of fly ash was again not comparable to mix designs with slag and silica fume.

5. As per observed durability results, use of silica fume in combination with slag would be a preferred option in marine concrete within their optimal ranges as defined in the literature. Addition of calcium nitrate as corrosion inhibitor is expected to produce better performance in resisting corrosion.
6. Use of pozzolans provides a sustainable means of construction material. Not only natural resources can be conserved by replacement of OPC by these pozzolans within their optimal ranges, but it can be a greater step for cutting down energy usage and CO_2 emission during cement production which is one of the most demanding materials being used around the world.

CAPILLARY ABSORPTION OF UNSATURATED CONCRETE SUBJECTED TO SUSTAINED COMPRESSIVE LOADING

J.W. Bao[1,*], L.C. Wang[1], B.J. Cheng[1]
[1]State Key Laboratory of Coastal and Offshore Engineering, Dalian University of Technology, Dalian, Liaoning, China, E-mail: baojiuwen55@126.com; wanglicheng2000@163.com;

ABSTRACT

Water penetration into concrete is one of the main factors to cause the deterioration of structures and chloride-induced reinforcing steel corrosion. External sustained mechanical loadings can substantially change the internal pore-structure of concrete and then lead to microcracks, which play a critical role in the durability of concrete because of the provision of additional pathways for aggressive agents (such as chloride ions, sulfate, oxygen, carbon dioxide etc.) to ingress into concrete. This paper presents an experimental investigation into capillary absorption of unsaturated concrete subjected to sustained compressive loading. In order to realize the couple of loading and water absorption process, the hollow cylinder specimens were loaded to different compressive loading levels, and simultaneously tested by an improved device for cumulative absorbed water measurement to conduct a series of water absorption experiments. The focus of this paper is to analyze the experimental results and quantify the influence of external loading and load-induced microcracks on the water absorption of concrete. According to unsaturated flow theory of concrete, the functional relationship with the stress level and sorptivity, which can characterize the tendency of concrete to absorb and transmit water by the capillary mechanism, is reasonably proposed for analyzing the effect of different compressive loading levels on water transport properties. The experimental results indicated that with the increase of applied compressive stress, the rate of capillary absorption of load-damaged concrete initially decreases, and with a further increase in stress level, one markedly increases.

KEYWORDS

Unsaturated concrete, water penetration, capillary absorption, sorptivity, sustained compressive loading.

INTRODUCTION

Degradation of concrete structures (e.g. bridge pier, dam, breakwater) occurs due to water transport between the environment and the multi-scale pore structure of material. Most familiar deterioration processes can be summarized as the corrosion of steel reinforcement, sulfate and chloride attack, frost damage, and so on (Aldea *et al*. 1999; Yang *et al*. 2006). In each of these processes, water is either the main agent responsible for the deterioration of concrete or the principal transporting medium carrying with aggressive species to ingress into concrete (Abyaneh *et al*. 2014; Hall 1989; Wang and Ueda 2011b). The mechanisms of water penetration into unsaturated concrete are mainly summarized as the permeability and capillary absorption. Permeability is usually an important indicator defined as the movement of fluid through a porous medium under an applied

pressure head while capillary absorption is described as the ability of water uptake in porous concrete material. Many researchers pointed out that the internal pore structure of concrete, its size distribution, as well as the microcracks within concrete determine the rate of capillary absorption (Hall 1989; Martys and Ferraris 1997; Yang *et al*. 2006). The internal pore structure of concrete when subjected to external mechanical loadings will be changed or interconnected and more new microcracks may occur, resulting in the change of water transport rate in concrete (Şahmaran and Li 2009; Samaha and Hover 1992).

Considerable efforts have been by far dedicated to investigate the influence of cracking or load-induced microcracks on mass transport in concrete. Most of them are mainly related to chloride penetration into saturated/unsaturated or cracked/uncracked concrete (Boulfiza *et al*. 2003; Wang and Ueda 2011a). The previous works have found that cracks created by naturally loading or artificially cutting a specimen can provide a preferential pathway for fluid to flow and concluded the quantitative relation between the chloride diffusivity and crack width (Aldea *et al*. 1999; Djerbi *et al*. 2008; Šavija *et al*. 2013; Wang *et al*. 1997). However, in reality the concrete structure may be always under the stress state and may have some microcracks, not cracked concrete. With time the applied loads promote crack growth and interconnectivity and in turn, result in an increase of transport rate in concrete. Moreover, water is treated as the principal transporting medium carrying with aggressive species to ingress into concrete. The clear understanding of water transport in concrete under loading will be beneficial to investigate the effect of aggressive species on the corrosion of steel reinforcement. Nevertheless, since the sorptivity of concrete should be inversely correlated with its degradability, capillary absorption performed on concrete specimens subjected sustained mechanical loading can provide useful information concerning quality control and the determination of which samples are likely to have a longer service life.

The effect of external mechanical loading on mass transport in concrete has attracted more and more attention in recent years (Aldea *et al*. 2000; Choinska *et al*. 2007; Hearn 1999; Samaha and Hover 1992; Sakoi and Horiguchi 2006; Tegguer *et al*. 2013; Yang *et al*. 2006; Wang and Li 2014). Hearn (1999) conducted the water permeability of concrete tested after unloading (uniaxial compression stress levels of 0.3, 0.5, 0.7 and 0.8) and found that the load-induced cracks have no remarkable effect on the permeability of concrete due to the significant elastic recovery of the cracked concrete. Yang *et al*. (2006) reported an investigation of water transport in concrete damaged by tensile loading and freeze-thaw cycling. They pointed that freeze-thaw damage resulted in a well distribution crack network throughout the concrete to facilitate water absorption while tensile loading had a little increase of that on a local level. Wang and Li (2014) investigated the effect of capillary absorption of concrete after being subjected to uniaxial compressive or tensile loading by a series of water absorption experiments (three load levels: 70%, 80% and 90%). They found that the rate of capillary absorption load-damaged concrete is approximately double of sound concrete within the scope of load level studied. Unfortunately, most of them investigated the effect of loads on water transport after unloading due to the diffusivity of the couple with loading and mass transport. So the transport properties of capillary absorption in unsaturated concrete subjected to external sustained loading have not yet been made clear, especially lack of some experimental data to explain this phenomenon. Therefore, there is still much work to be done to give a quantitative relationship between the sorptivity and stress levels. It is necessary to make further attempts to quantify how transfer water into unsaturated concrete subjected to external sustained loading.

The current paper attempts to gain more insight on the transport properties of capillary absorption under stress and conducts an experimental investigation into capillary absorption of unsaturated concrete subjected to external sustained compressive loading. The hollow cylinder test specimens under sustained compressive

loadings were moved to an improved device for cumulative absorbed water measurement to conduct a series of water absorption experiments, realizing the couple of loading and water absorption process. The unsaturated flow theory of concrete is utilized to predict the water distribution by means of the functional relationship with the stress level and sorptivity experimentally proposed for analyzing the effect of different compressive loading levels on water penetration property.

CAPILLARY ABSORPTION OF UNSATURATED CONCRETE

Unsaturated flow theory, which is widely adopted to describe water uptake in soil, can be utilized to explain water transport in partially saturated concrete (Goual *et al*. 2000; Hall 1989; Leech *et al*. 2003; Lockington 1993). According to the following assumptions: i) concrete being taken as the porous and semi-infinite media; ii) ignoring gas phase of water; Combining with the mass balance equation, the equation for unsaturated flow through porous media is expressed by combination of the extended Darcy's equation due to capillary pressure gradient (Hall 1989):

$$\frac{\partial \theta}{\partial t} = \nabla\left[D(\theta) \cdot \nabla \theta \right] \tag{1}$$

where t is the absorption time; dimensionless variable the relative water content θ is scaled to be zero and one for the initial and saturated volumetric water content (i.e. volume of water/bulk volume of concrete), Θ_i and Θ_s, respectively. Thus θ can be written as $\theta=(\Theta-\Theta_i)/(\Theta_s-\Theta_i)$, in which Θ is the volumetric water content under any state, ranging between Θ_i and Θ_s. $D(\theta)$ is a material property, generally called the hydraulic diffusivity with dimensions $\mathbf{L^2T^{-1}}$, which depends both on the type of material and the water content (Leech *et al*. 2003; Lockington 1993).

Using the Bolzmann transform, $\phi=xt^{-1/2}$, Eq. (1) for a one-dimensional semi-infinite system is reduced to an ordinary differential equation as follows:

$$-\frac{1}{2}\phi \frac{d\theta}{d\phi} = \frac{d}{d\phi}\left[D(\theta) \frac{d\theta}{d\phi} \right] \tag{2}$$

The approximate analytical solution of Equation (2) with a very high accuracy has been proposed by Parlange *et al*. (1984) as follows:

$$\frac{A}{2}\phi^2 + s\phi - 2\lambda(\theta) = 0 \tag{3}$$

where s is the normalized sorptivity; the parameters A and $\lambda(\theta)$ are related with $D(\theta)$. These formulas can be given as follows:

$$s = \frac{S}{\Theta_s - \Theta_i} \cong \left(\int_0^1 (1+\theta) D(\theta) d\theta \right)^{1/2} \tag{4}$$

$$A = 2 - \frac{s^2}{\int_0^1 D(\theta) d\theta} \tag{5}$$

$$\lambda(\theta) = \int_\theta^1 \frac{D(a)}{a} da \tag{6}$$

where the sorptivity S can be experimentally obtained by the absorption test. Obviously, using the exponential-law and power function of $D(\theta)$, the expressions of above-mentioned parameters can be presented

as shown Table 1. Finally, the formula of water penetration depth predicted under sustained loading is obtained as

$$x = \phi\sqrt{t} = \frac{-s + \sqrt{s^2 + 4A\lambda(\theta)}}{A}\sqrt{t} \tag{7}$$

where x means the depth from exposed surface, which is mainly related to the normalized sorptivity of concrete.

Table 1 Parameter expressions of two kinds of diffusion coefficient

Exponential-law ($D(\theta)=D_0e^{n\theta}$)	Power function ($D(\theta)=D_0\theta^n$)
$A=\frac{e^n-n-1}{n(e^n-1)}$	$A=\frac{1}{2(2+n)}$
$\lambda(\theta)=D_0\left\lfloor\sum_{N=1}^{\infty}\frac{n^N}{N\cdot N!}(1-\theta^N)-\ln\theta\right\rfloor$	$\lambda(\theta)=\frac{D_0}{n}(1-\theta^n)$
$D_0=\frac{n^2s^2}{e^n(2n-1)-n+1}$	$D_0=\frac{(1+n)(2+n)s^2}{3+2n}$

EXPERIMENTAL PROGRAM

Materials and specimen preparation

A group of water absorption experiments were designed and conducted on concrete samples subjected to uniaxial sustained compressive loading within various levels. The concretewas designed with water/cement (w/c) ratio of 0.45. Ordinary Portland cement 32.5R (type CEM based on the Chinese code) was used. A locally available limestone aggregate with a maximum size of 20mm was used as the coarse aggregate. A locally available river sand with the fineness modulus of 2.67 and apparent specific gravity of 1450 kg/m^3 was used as the fine aggregate. In addition, a water-reducing admixture was added at 0.2% by weight of cement to achieve a slump with the range of approximately 65~80mm. Details of the mixture proportion are listed in Table 2.

Table 2 Mixture proportions for concrete (kg/m^3)

Cement	Coarse aggregate	Fine aggregate	Water	Water reducer	w/c
422.5	1251.25	536.25	190	0.845	0.45

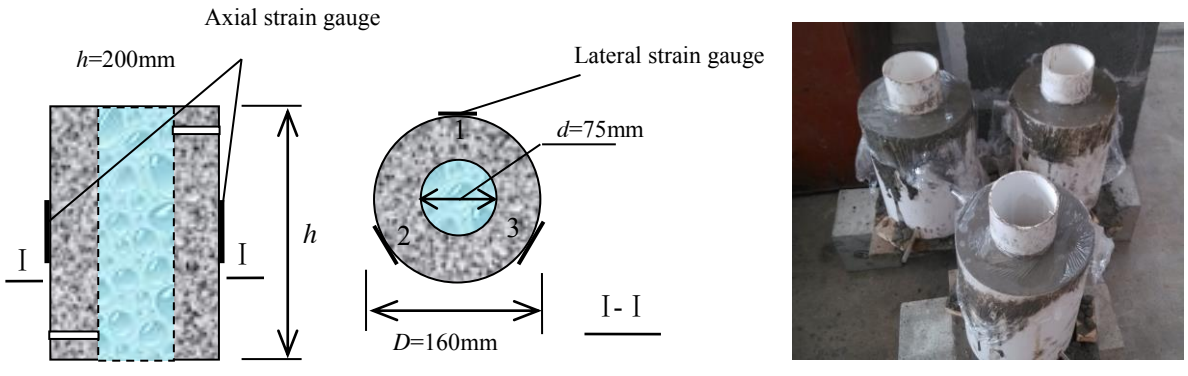

Figure 1 (a) Geometry of the specimen; (b) Concrete casted with PVC tubes

Three specimens used for the compressive strength test were cubes with dimensions of 150 mm×150 mm×150 mm. The cubic compressive strength at 28 days is 44.2 MPa. In order to realize the couple with loading and water absorption process, the hollow cylinder specimens were cast in 200×160 mm-diameter plastic molds (Figure 1). After finishing, the specimens were covered with a plastic sheet and stored wet at room temperature of 23 °C for 24h. Then the internal PVC tubes of specimens were de-molded. The samples were cured in moist room (>95% relative humidity) at 23°C until the time of test. Before loading and water absorption, the test samples were oven dried at 105°C to constant weight.

Water absorption test under sustained compressive loading

After the sealing of epoxy and cover plates, the hollow cylinder specimens were loaded to pre-estimated stress levels using 3000kN compression frame for obtaining the sustained loading and conducted at the same time water absorption test (see Figure 2). The improved test setup adopted the principle of communicating vessel that can realize the couple of water transport and loading and ensure the continuity of water absorption process. The apparatus consists of a water injection funnel to maintain the water supply and a tube with scale used to timely measure the change of water volume. The device is integrally connected with the hollow cylindrical specimen. After 36h testing, the hollow concrete cylinders were sequentially loaded to obtain the real compressive strength (as shown Table 3). The axial contraction of the specimen was monitored by the average of the data of two linear variable displacement transducers (LVDT) placed on the lateral side of specimen. During loading, the stress-strain responses were recorded by three lateral and two axial strain gauges (Figure 1a). In order to analyze the influence of compressive stress on the sorptivity, the stress level, λ_c, is defined as the ratio between the applied stress (σ_c) and the measured strength of the concrete (f_c):

$$\lambda_c = \frac{\sigma_c}{f_c} \times 100\% \tag{8}$$

The relationship curves of different compressive stress levels versus axial, lateral and volumetric strains are shown in Figure 3.

RESULTS AND DISCUSSION

Cumulative water content

Cumulative water content, i(mm), is defined as the cumulative volume of water absorbed per unit inflow surface area and increases with the square root of elapsed time (Hall 1989):

$$i = \frac{\Delta m}{\rho_w A_c} = S\sqrt{t} + b \tag{9}$$

in which Δm is the weight of absorbed water at the given time (g); ρ_w is the density of water (g/mm^3); The sorptivity S presents the rater of water absorption in porous materials; b is a correction term accounted for surface effects at the time the specimen is placed in contact with the water; A_c is the cross-sectional area of the water exposed surface (mm^2), but for the hollow cylinder specimens, it is rather than constant and increases with

the increase of radius. In order to simply describe 1D water transport, from the view of the saturated porosity of concrete, a correction factor β of this simplified method is defined as (as shown Figure 4)

$$\beta = \frac{r + d/2}{d} \tag{10}$$

where r means the average radius of specimen sample at a given time.

Hansen (1986) pointed out that the fractional volumes of all major constituents in the physical structures of cement paste can be estimated from the water-cement ratio (w/c) and the degree of hydration of the cement past (α), and the total porosity under unstressed state p_0 can be written as

$$p_0 = \frac{w/c - 0.17\alpha}{w/c + 0.32} \tag{11}$$

According to previous studies, the effect of the external mechanical loading on the chloride diffusivity in concrete is treated as the change of porosity on the chloride diffusivity. As shown in Figure 5, the impact factor λ_p of the porosity under sustained compressive loadings can be written by fitting regression of experimental results (Sakoi and Horiguchi 2006; Rahman *et al*. 2012; Teggure *et al*. 2013). Typical results of cumulative water content in unsaturated concrete subjected to various sustained compressive loadings are presented in Figure 6. It can be seen that the changing porosity or microcracks caused by sustained compressive loading has an apparent influence on cumulative water content.

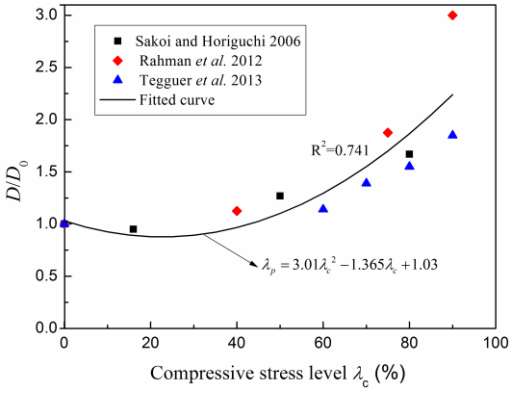

Figure 5 Relationship between the diffusivity and compressive stress level

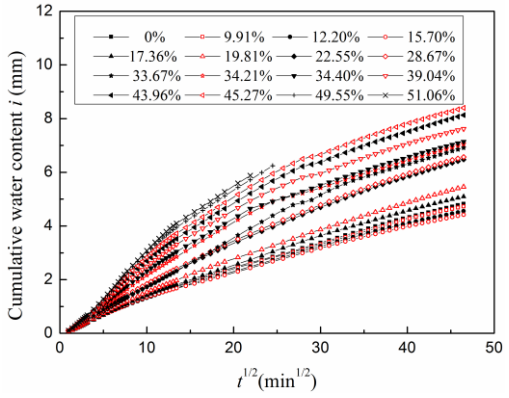

Figure 6 Effect of different stress levels on cumulative water absorption

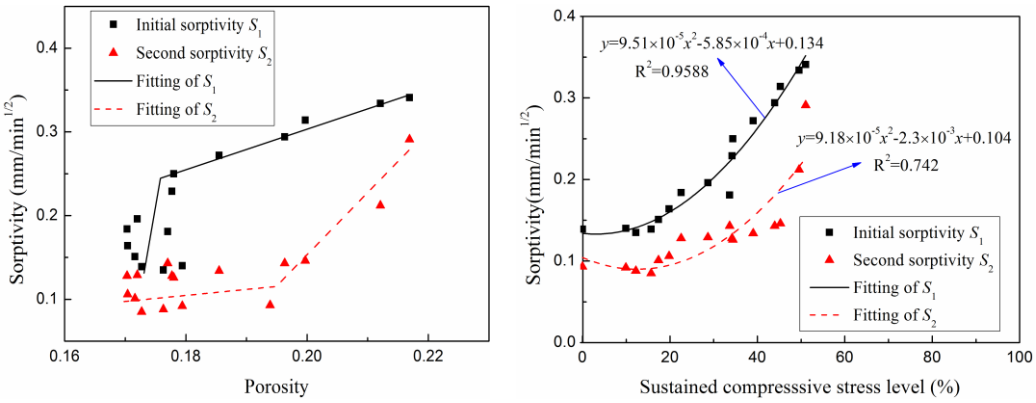
Analysis of sorptivity

The sorptivity of unsaturated concrete measures the ability of this porous material to transfer fluids under a gradient of capillary pressure, which is a key parameter for assessing the service life of concrete structures exposed to some harsh environments (Hall 1989; Wang and Ueda 2011a). The water uptake depends largely on inherent microcracking within the concrete and the interconnected pore network within the hydrated cement paste induced by the external mechanical loadings. Yang *et al*. (2006) pointed out that two linear portions respectively corresponded to the rapid saturation of capillary pores and the slow filling of air voids. From Figure 6, these curves can in principle reflect the initial absorption and much longer absorption. Based on above-mentioned Equation 9, the initial and second sorptivity (S_1 and S_2) can be reasonably calculated. Figure 7 has presented the effect of sustained compressive load level and porosity on the two corresponding sorptivities. The initial rate of water absorption is apparently higher than the second phase of ones. One can see that the initial sorptivity is more sensitive to the porosity than the second sorptivity as a result of the interconnectivity of pores in the cement paste and microcracking in the concrete, especially in the interfaces between aggregates and

cement pastes. Sustained compressive loadings can make this interconnectivity and microcracking stable. It is observed that there is slightly decrease of sorptivity in the sustained compressive load level below 30% due to the axial compaction of concrete. At this stage, the loading has no influence of the pores in cement paste and microcracks of interface. However, with the increase of load levels, when λ_c>30%, the initial and second sorptivities of unsaturated concrete have a greater increase. Meanwhile, it suggests that the sustained loading results in the pores interconnected and more new microcracks may develop and propagate. The functional relationship between the stress level and sorptivity is obtained by fitting test data for analyzing the effect of different compressive loading levels on water content distribution.



(a) (b)

Figure 7 Effect of sustained compressive load level and porosity on the sorptivity

Prediction of water content distribution

As shown in Figure 7b, the experimentally obtained relationship curves between sustained compressive stress level and sorptivity can be adopted to predict water content distribution in concrete under any stress states. Based on the unsaturated flow theory of capillary absorption, five kinds of sustained compressive stress levels of 0%, 10%, 30%, 50% and 70% were chosen to conduct the predictions of water distribution after various elapsed times as shown in Figure 8. The penetration depths of water calculated by two kinds of diffusivities (exponential-law and power function) are compared. One can find that the stress level below 30% has no greater influence on the penetration depth of water, but with a further increase in stress level, one markedly increases.

CONCLUSIONS

In the present paper, an improved test setup for measuring the sorptivity of concrete subjected to sustained compressive loadings was developed to investigate the effect of the internal pore-structure or microcracks on water absorption. The functional relationship between stress level and sorptivity is reasonably proposed for analyzing the effect of different compressive loading levels on water transport property. Combined with unsaturated flow theory and the available experimental findings, the exponential-law and power function of diffusivities are adopted to conduct the prediction of water distribution under some stress states after various elapsed times. The experimental results indicated that with the increase of applied compressive stress, the rate of capillary absorption in load-damaged concrete initially decreases (stress level lower than 30%), but it has a sharp increase with a further increase in stress level. The lower sustained compressive loading has no influence of the pores in cement paste and microcracks of interface while the upper one can change the pore structure and even make the interfacial crack or microcrack develop and propagate, resulting in the change of transport property. Similarly, the presence of a compressive stress below this threshold value has no influence on the depth of water penetration into concrete, but when the applied stress exceeded this threshold, a significant increase in the depth occurred.

ABSTRACT

Bridges are an essential part of the transport infrastructure. A considerable number of these bridges are metallic, in many cases exceeding 100 years of age having suffered deterioration from environmental attack such as atmospheric corrosion. In order for infrastructural managers to make informed decision in terms of life-cycle cost perspective, reliable prediction of the remaining strength and service life of deteriorating bridges is essential. Deterioration models have been developed over the years to predict long-term material loss under different atmospheric conditions and environments. The aim of this paper is to quantify the effects of long-term deterioration, based on these models, on the remaining strength of metallic bridge girders, comprising of a number of plates. To obtain a useful insight into this problem, the finite element method is employed. In this paper, different plate elements, of varying slenderness and boundary conditions and representative of real bridge configurations, are analysed under different deterioration scenarios, brought about through material loss at different locations of the element. The effects of various parameters such as the degree/severity of material loss and the corrosion pattern (uniform versus non-uniform) on the buckling strength of the plates are quantified through both linear eigenvalue and non-linear analyses. The results of this study show that critical buckling strength of web panels may significantly drop at higher percentages of corrosion degradation and patterns, with the failure mode likely to change with increased deterioration. Differences between the critical buckling stresses obtained from the linear and non-linear analyses are presented.

INTRODUCTION

Since the start of civilisation bridges for roads, railways, walkways and canals have been built, therefore it is impossible to conceive today's world without bridges (Biezma and Schanack 2007). One of the main construction materials for these bridges is steel. Most metallic bridges are made of carbon and low alloy steel (i.e. steel with carbon content in the range of 0.12-2.0% as the main alloying constituent) due to the competitive initial cost advantage of this material over others like aluminium and stainless steel products (Gardner et al. 2007). Though the later material tends to be gaining recognition recently owing to it its whole-life-cycle cost advantage over time but a large stock of existing metallic bridges are made of carbon steel. Every bridge exists in an environment, and in this environment of existence these bridges suffer from atmospheric corrosion due to exposure to the environment. The long-term deterioration of these metallic bridges is triggered by this exposure condition which is defined by environmental and atmospheric parameters like relative humidity, temperature, pollutants and time of wetness. These parameters expedite the deterioration process including the rate of corrosion (Kallias and Imam 2013). Giving the global challenge of climate change on the environment, it is thought that the environment of existence of these bridges is also changing accordingly which may, in turn, influence the deterioration rates.

Corrosion is one of the important factors that reduce structural capacity during service life (Saad-Eldeen *et al*. 2013). Corrosion can cause three basic changes in steel: loss of material, reduction of section parameters and building of corrosion products (Cruz *et al*. 2006), as shown in Figure 1. Usually, at the design stage, a corrosion

thickness allowance is added to compensate for the potential thickness reduction due to corrosion over service life of the structure (Saad-Eldeen *et al*. 2013). Protective coating are also applied to metallic surfaces to prevent or slow down corrosion. However, successful history of steel bridges has not and is not without catastrophes (Biezma and Schanack 2007).

Structural design involves description of structural behaviour and strength prediction. Therefore, the assessment of strength, stiffness and stability requires the evaluation of the structural capacity of the structural components that makes up the structural system. For bridges, plate girders are an important structural component because of their ability in load resistance. Plate girders are mainly made of plates and are provided when hot-rolled sections show insufficient strength or are not economical for design purposes (Cruz *et al*. 2006). Modern plate girders are often made by welding plates together whereas, in older bridges, riveted built-up girders was the main way of constructing them. Corrosion can appear in different forms. Uniform corrosion manifests itself through a uniform thickness reduction across a large area over a structural member. On the other hand, more localised corrosion can appear in terms of pitting corrosion or pit holes. Corrosion can also be non-uniform showing different severity and extent over a structural member. Field experience has shown that the bottom parts of plate-girders can be more susceptible to corrosion losses due to the accumulation of dirt and water over time.

The aim of this paper is to investigate the long-term deterioration effects on buckling strength of metallic bridges using numerical analysis. A range of plate elements, with varying slenderness, representing elements used as part of bridge girders are analysed through linear and non-linear buckling analysis under different deterioration scenarios assumed through material loss at different locations of the element. The effects of various parameters such as the degree/severity of material loss and the corrosion pattern (uniform versus non-uniform) on the buckling strength of the plates are quantified.

Figure 1 Corroded railway plate girder Bronx- Edenwald, USA.

Corrosion Damage Assessment

(BS EN ISO 9223 2012) classifies atmospheric corrosivity into two categories: classification based on corrosivity determination by corrosion rate measurement on standard coupons, and classification based on estimates of corrosivity based on environmental information. This paper considers corrosion damage assessment based on environmental information considering expected potential changes in the climate over the design life span of the bridge, i.e. 120 years. The dose-response function relative to carbon steel was used as presented in equation (1) below.

$$r_{corr} = 1.77{P_d}^{0.52}.\exp(0.020RH + f_{st}) + 0.102{S_d}^{0.62}.\exp(0.033RH + 0.040T) \quad (1)$$

where f_{st}=0.150(T-10) when T≤10ºC otherwise -0.054(T-10), T=Temperature in ºC, r_{corr}=1st year corrosion rate of metal in μ_m/year, RH=relative humidity in %, P_d=SO_2 deposition in mgm^{-2}day^{-1} and S_d=Cl^- deposition in mgm^{-2}day^{-1}.

Equation (1) estimates the first year corrosion while equation (2) below, given in (BS EN ISO 9224 2012) estimates corrosion attack (D) beyond the first year.

$$D = r_{corr} t^b \tag{2}$$

where t=exposure time in years, b=metal-environment-specific time exponent usually <1.

Equation (2) predicts corrosion loss up to twenty years followed by corrosion product layer protection which slows down the rate of corrosion after the first twenty years. The relationship is exponential within the first twenty years after which it becomes linear. To capture behaviour after the first twenty years Equation (2) is differentiated with respect to time to give the rate of corrosion.

$$\frac{dD}{dt} = b r_{corr} t^{b-1} \tag{3}$$

The corrosion attack from year 20 onwards is given by

$$D(t > 20) = r_{corr}\left(20^b + b(20^{b-1})(t - 20)\right) \tag{4}$$

Results from equation (4) were used as a guide for the parametric studies presented in this paper.

PLATE GIRDERS

Plate girders are used in both road and railway bridges, sometimes in buildings when high loads and/or large spans are envisaged. They are made of steel plates which are usually welded or bolted/riveted together to form an I-section (Clarke and Coverman 1987). One advantage of plate girders is that they can be built to any size to meet with design requirement but, their geometrical proportions are usually governed by web buckling. Stiffeners are used to strengthen the web for increased allowable buckling stress. For long span construction where rolled beams are not adequate, generally the choice is between the use of compound beams or plate girders. In modern bridges where continuous construction is used to reduce maximum moments, plate girders may not be required until the span exceeds about 25m. Generally, these built-up standard beams are more economical when they are below 25m span. But currently, plate girders spanning 60-100m are in use owing to the introduction of automatic welding techniques and the development of steels which allow the use of normal procedure for welding thick plates thus reducing fabrication cost. Box girder decks are also made of slender plates welded together. Older bridges are made up of a number of plate elements and/or angles riveted together to form I-sections or other cross-sectional types used for example in truss bridges as top/bottom chords, hangers and diagonal members.

BUCKLING BEHAVIOUR OF PLATE GIRDERS

Buckling is a nonlinear phenomenon whereby a structure cannot any further take up load with its original geometry and so it changes its shape in order to find an alternative equilibrium position (Sosa *et al*. 2006). The way in which buckling occurs depends on how the plate is loaded, its geometrical and material properties as well as the boundary conditions. If the plate is loaded such that most of its strain energy is in the form of membrane compression, and if there exist an opportunity that this stored-up membrane energy can be converted into bending energy, buckling occurs (Bushnell 1981). Usually, plate membrane stiffness is by far greater than the bending stiffness and a thin plate can absorb most of the membrane energy without deforming too much, but for it to absorb an equivalent amount of bending strain energy it must deform much more (Bushnell 1981). So generally, when large deformations exist it converts the membrane energy into bending energy which results in buckling.

FINITE ELEMENT MODELLING

Preamble

Numerical methods, mainly finite element analysis (FEA), remain the most advanced tool in rational structural analysis which makes it possible to predict the strength of complex structures more accurately when compared to classical theoretical methods (Ok *et al*. 2007; Saad-Eldeen *et al*. 2013). Therefore, this section deals with the aspect of linear and nonlinear FEA used to evaluate the typical response of uncorroded and corroded plate girders. As mentioned earlier, plate girders can be built to any size but the geometrical proportion is being

governed by web buckling. This paper presents results of corrosion degraded web plates under compressive uniaxial loads.

Problem Description

Three different models differentiated by their slenderness (width to thickness) (b/t) ratio were analysed. The models were designated as slender, intermediate and stocky with slendernesses equal to 107, 71 and 28 respectively. Generally, the models had an aspect ratio of 2 based on the plate dimensions of 856mm × 428mm and thicknesses of 4, 6 and 15.3mm respectively. The material is assumed to be isotropic elastic with young modulus (E) of 206,000N/mm^2, Poisson's ratio (ν) of 0.3, yield stress (σ) of 275N/mm^2 and ultimate strength of 485N/mm^2. The material stress-strain law adopted herein followed the 2nd distribution on Figure 5. Figure 5 defines the frequently used material constitutive law in numerical studies, and these are generally assumed to represent the actual behaviour of structural steel (Boissonnade and Somja 2012).The boundary conditions on the model are simply supported therefore a buckling coefficient (K) of 4 is used.

Methodology

The problem at hand is a stability issue and nonlinear stability studies will require two types of analyses: linear eigenvalue analysis and postbuckling or collapse analysis. The eigenvalue analysis is a required step for the more general collapse or load-displacement response. The general purpose nonlinear finite element commercial code ABAQUS/Standard is used for the analysis (Simulia 2014). Since corrosion degradation leads to section thickness loss, one of the nonlinear behaviours expected is geometric nonlinearity which may lead to large displacement effects. So to activate the large-displacement formulation capability, ABAQUS requires that in the *STEP module, the general static Riks procedure type should be engaged.

Including nonlinear effects in an ABAQUS simulation involves defining either geometric, boundary or material nonlinearities. Geometric nonlinearity include all nonlinear geometric effects due to large deflections, rotations, deformations, preloading and load stiffness. If the mentioned effects are not significant, the predicted model response will be as if the *Nlgeom in the step module were set to off. Boundary nonlinearity involves defining contact interactions between bodies. While modelling material nonlinearity involves defining material properties like plasticity and hyperelasticity. Results in this paper were computed taking into account both geometrical as well as material non-linearity in order to capture the elasto-plastic behaviour of the analysis.

FE MODEL VALIDATION

Eigenvalue Analysis

To validate the FE models used in this study, two versions of each model i.e. slender, intermediate and stocky plates were used: first plate to conduct the eigenvalue buckling analysis and the second to carry out the Riks control analysis.

The eigenvalue buckling analysis was used to obtain estimates of critical load (limit load) at which the response of the structure will bifurcate, assuming that the response prior to bifurcation is essentially linear. The aim was to investigate singularities in a linear perturbation of the structure's stiffness matrix thereby understanding the structure's maximum sustainable load. The eigenvalue analysis was also useful in providing guidance about the finite element mesh design, element type selection and the appropriate boundary conditions to be used.

Results from the linear eigenvalue FEA were compared to buckling theory through

$$\sigma_{cr} = \frac{K\pi^2 E t^2}{12(1-\vartheta^2)b^2} \tag{4}$$

where σ_{cr} =critical buckling stress, k=buckling coefficient, E=modulus of elasticity, t=thickness, b=width, ϑ=Poisson's ratio

The buckling mode shapes were also investigated to see how consistent they are with typical buckling modes, as shown in Figure (2).

Table 1 presents results from these analyses. As it can be seen, very good agreement between the FE results and the theoretical values is obtained validating the way the plate was modelled in the FE software and the number of elements used as a mesh.

Riks Control Analysis

The next phase of the validation process was performing the full nonlinear load-displacement analysis on the same models (As-new) to investigate whether the eigenvalue buckling prediction already obtained was accurate and at the same time check whether the model is imperfection sensitive. The Riks control analysis is one that overcomes the limitations of both the load and displacement control analyses. The load control analysis can only provide response up to the limit load giving solver limitation of matrix inversion, while the displacement control takes the response beyond the limit load to capture elasto-plastic behaviour in the direction of positive displacement however, limited by snap-back response. However, the Riks analysis is able to provide response past these limitations using a nonphysical variable called the arc-length which enables the postbuckling and collapse behaviour to be captured. Therefore, in this analysis both geometric and material nonlinearities were factored in to improve model fidelity. Table (2) presents results from the nonlinear analysis while Figures (3) and (4) show the load-displacement response for the as-new plates. As can be seen, non-linearity, both material as well as geometric, plays an important role in reducing the critical buckling strength of a plate. This shows the importance of the need to carry out non-linear analysis as it demonstrates that by running solely linear eigenvalue analyses, this will not provide a realistic representation of the buckling strength reduction of plates of these proportions.

Table 1 Linear eigenvalue critical buckling stress

Plate ID	Slenderness (b/t) ratio	Critical buckling stress (N/mm^2)		% Difference	Number of Elements	Element type
		Theoretical	Finite Element			
Slender	107	65.1	63.0	-3.2	7040	C3D20R
Intermediate	71	146.4	141.4	-3.4	7040	C3D20R
Stocky	28	952.0	903.1	-5.1	6400	C3D20R

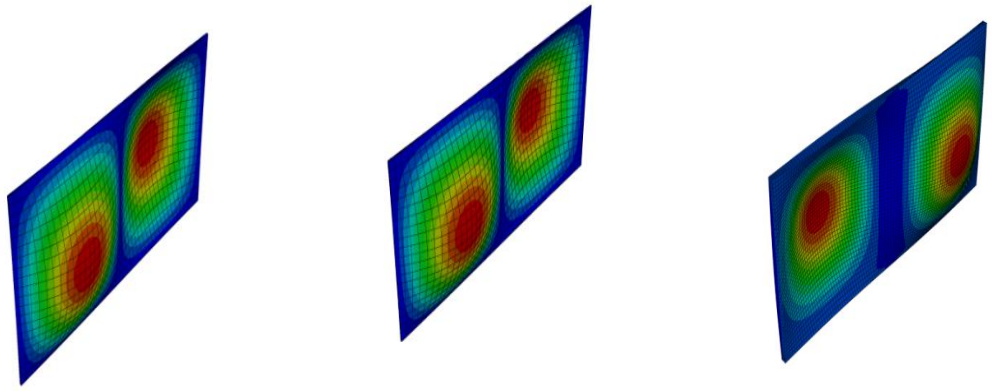

Figure 2 FE mode shapes for slender, intermediate and stocky plates respectively

Table 2: Comparison of linear and nonlinear critical buckling stress

Model ID	Slenderness (b/t)	Critical buckling stress (N/mm^2)			
		Theoretical	Linear eigenvalue	Nonlinear value	% difference between linear & nonlinear
Slender	107	65.1	63.0	42.5	-32.6
Intermediate	71	141.4	141.4	94.3	-33.3
Stocky	28	952.0	903.1	280.0	-68.9

PARAMETRIC STUDIES

In other to assess the long-term reduction of buckling strength due to corrosion effects, parametric analyses were carried out on corroded models, see Figure (7) for geometric parameters. Plate section thickness was considered

to be lost at 10%, 30%, 50%, 70% and 90% of the original thickness (t) of each plate model of slender, intermediate and stocky. The models were considered under uniform corrosion scenario as well as non-uniform corrosion scenario. The models were loaded in uniaxial compression as a uniform pressure. In order to capture the non-uniform corrosion patterns on the FE models, solid elements have been used for the analysis, due to the inability of shell elements to model such patterns. The static, Riks algorithm procedure was followed for a geometric and material nonlinear analysis with 10% initial geometric imperfection, following the first eigenmode, as a function of the plate thickness in order to initiate buckling. As validated, the mesh design sensitivity was between 20-25 seeds generating between 6000-9000 elements. The Kirchoff theory for thin plates is assumed considering large displacements and small strains.

For the non-uniform corrosion scenario, two parametric conditions were considered. The first one was the ratio between corroded depths (b_c) over whole depth (b) i.e. b_c/b (see Figure 7) is varied in percentages of 10%, 30%, 50%, 70%, 90% and 100% while the thickness loss (t_c) is kept constant at 30% in one occasion and 50% in another. The second condition is where the aforementioned condition was reversed at similar percentages. Tables (3) & (4) present results from the uniform corrosion scenario whereas Table (5) shows the results from the non-uniform corrosion scenario.

DISCUSSION OF RESULTS

Combining results of the rate/degree of corrosion as well as the type, the following predictions were made on the elastic and post-buckling critical buckling stress of the web panel. From the results presented in Tables 3, 4 and 5, it can be seen that the critical buckling stress of web panel drops with increasing thickness and corrosion depth damage. A 30% loss of plate thickness can be seen to result in about 50% decrease of the buckling strength for the slender and intermediate plates. Even a 10% loss in thickness may result in 20% decrease of strength, demonstrating the fact that even low levels of corrosion loss can have a significant effect on buckling strength. It is observed that the behaviour of the slender and intermediate plates are similar in Figure (6) and both failed due to buckling, whereas, the stocky plate show yielding failure behaviour. Yielding failure is ductile in nature, therefore it provides warning before collapse (Kayser and Nowak 1989). Of course, the stocky plate's estimated critical strength is greater than the material strength hence the yield failure. But as it is damaged by corrosion an increase in slenderness (b/t) ratio is observed over time (see Table (3)) and once its slenderness approaches the intermediate to slender regime, its behaviour changes accordingly leading it to fail due to buckling.

Corrosion loss is also seen to reduce the geometrical section properties because of the reduction in section area. This happens in a nonlinear fashion because such properties like second moment of area (I) or radius of gyration (r) are related to the square or cubic dimensions (Kayser and Nowak 1989). Table (3) shows that stiffness is lost at almost the same percentage with the deterioration, hence the loss in buckling capacity as these geometrical stiffness functions are affected. Again, the shear resistance of the web may be affected because of the corrosion degradation and the web is known to majorly sustain the shear force. Because of this web function, it is usually designed to operate at elastic nonbuckling stress levels (Kayser and Nowak 1989). Therefore, if the failure mechanism changes from yielding to buckling as seen in Tables (3) & (4) due to section loss for the stocky plate, shear capacity might degenerate rapidly more so that the section classification might change. Hence, this demonstrates the need for further investigating in detail shear behaviour as well to understand more deeply the instability phenomena.
The bearing capacity of a plate may be affected by corrosion. Bearing forces are primarily resisted by the web, immediately above the support (Kayser and Nowak 1989). This is why webs are generally reinforced by stiffeners especially above intermediate supports. At the time of construction a girder may not require a stiffener but when affected by corrosion over time, stiffeners are very necessary to maintain structural integrity. This is what a nonlinear analysis like this aimed to achieve: to detect the critical web region and what strength reduction is possible.

Table 5 shows the critical buckling stresses obtained for the non-uniform corrosion scenarios, assuming that only part of the plate deteriorates, as shown in Figure (7). Such tables may be extremely useful for the purposes of bridge element assessments, where following inspections and identification of corrosion patterns, bridge managers can estimate the potential loss of buckling strength through them. With additional analyses capturing the entire range of thickness and depth corrosion, as well as considering different plate dimensions (and therefore slendernesses), a number of spectra mapping buckling strength loss under different scenarios can be obtained.

The corrosion scenarios investigated in this paper have been done so in an incremental manner (see Tables (3) to (5)) to review the full range of variation of the buckling strength with respect to corrosion. Use of Equations (1) to (4) can aid towards predicting the effects of climate change on buckling strength through investigating the

influence of changes in the environmental parameters and/or atmospheric pollutants over time. By investigating different scenarios of changes in environmental conditions, the potential increase in corrosion loss can be quantified through these equations and use of Tables similar to (3), (4) and (5) will determine the reduction in the buckling strength brought about by the former.

CONCLUSIONS

The long-term deterioration effects on buckling strength due to structural exposure to changing environmental climate was investigated parametrically by combining information about the structure's location and rate of corrosion with FE analysis approach. Corrosion which results from such exposure can have a significant effect on compression strength because of the possibility of buckling. Plate elements made of carbon steel, typically representative of elements found on existing metallic bridges, subjected to uniaxial compression load, were studied in this paper.

Numerical analysis results illustrate that critical buckling strength of web panels significantly reduce at higher corrosion degradation. For example, 30% thickness loss in uniform corrosion can lead to a 50% strength loss in slender and intermediate plates but only 2% for the stocky plate. According to the obtained results the behaviour of slender and intermediate plates is similar and both fail in buckling, while the stocky plate illustrates yielding failure behaviour. However, when affected by corrosion this ductile yielding behaviour can be compromised because of corrosion effect on geometrical properties.

The obtained results were verified by well-established Euler buckling plate equations theoretically and the compatibility was good. Sensitivity analysis show that C3D20R quadratic solid elements seeded to between 20-25 seeds generating up to 6000-9000 elements on models allows for results convergence at a reduced computer running time because of the element reduced integration algorithm.

In the future this research will consider the effects of roughness, pitting and corrosion shape irregularity on strength. By investigating these scenarios, together with further parametric analyses capturing the entire range of corrosion losses both under uniform and non-uniform patterns, spectra mapping buckling strength loss on plates different proportions can be established. These can be extremely useful for the purposes of bridge element assessments where following bridge inspections, identification of potential corrosion can lead to a quick estimate of buckling strength reduction. A further extension on the effect of corrosion on the lateral torsional buckling resistance of built-up sections will also be considered.

ABSTRACT

Since deformation quantities have become principal design consideration in performance-based seismic design (PBSD), it is necessary to evaluate the deformation behavior of corroded RC structures for life-cycle oriented PBSD philosophy. Firstly, the material strain-based criteria to classify the performance limit states of RC beams and columns were proposed. Numerical analysis of corroded RC beams and columns in a wide range of design parameters was performed with the aid of ABAQUS finite element analytical program to evaluate the deformation behavior of corroded RC members. It is found that the corrosion ratio of reinforced bars has little effect on the deformation capacity of corroded RC members with low corrosion ratio. RC beams and columns with high corrosion ratio could fail due to the deterioration of bond between the concrete and longitudinal reinforcement, which induces significant degradation of deformation capacity of the structural member. The statistical characteristic values of deformation indexes corresponding to individual performance limit state of corroded RC beams and columns were obtained based on numerical analysis results. The research results can be utilized for life-cycle oriented seismic performance evaluation and design of RC structures.

KEYWORDS

Corroded RC beam, corroded RC column, deformation index, seismic performance level.

INTRODUCTION

The corrosion of steel reinforcement is detrimental to the serviceability and capacity of reinforced concrete (RC) structures. For RC structures located in earthquake-prone regions, reinforcement corrosion may gradually induce the degradation of structural members and increase their seismic vulnerability. A structure that is originally designed to meet code specifications may not have the same margin of safety once the structure has undergone significant corrosion (Choe *et al*. 2008). Due to the time-dependent nature of RC structures, it is suggested that seismic design of RC structures should consider the joint effect of seismic and aging threats.

The inelastic deformation capacity of RC members is important for the resistance of RC structures imposed to seismic loads because the earthquake resistant design relies on the ductility. Due to the emergence of displacement-based concept for seismic design of new structures and seismic evaluation of old ones, the quantification of deformation capacity of RC members has attracted increasing interest in recent years (Panagiotakos *et al*. 2001). The guidelines, known as FEMA 273 (FEMA 1997) and FEMA 356 (FEMA 2000), specified the deformation capacity of RC members in terms of geometric and mechanical characteristics of members and of their reinforcement. These studies focused on pristine (not corroded) RC structures, and the proposed deformation limits may not be appropriate once the structure begin deterioration from corrosion. In recent years, significant research efforts have been devoted to the evaluation of corrosion effects on the seismic performance and seismic fragility of RC structures (Ma *et al*. 2012; Ou *et al*. 2014). The previous studies provide a preliminary understanding on the seismic behavior of corroded RC structures. However, the further study on the performance index of corroded components has been rarely reported up to now.

Due to the emergence of the life-cycle oriented performance-based concept for seismic design of new structures and seismic evaluation of old ones in recent years, the quantification of seismic performance indexes for corroded RC structural components is needed. To this end, the main objective of this study is to evaluate the deformation limit of RC beams and columns corresponding to individual damage state, considering the effect of the performance deterioration induced by the steel bar corrosion. The material strain-based criteria were proposed to classify the performance levels of RC members.

PERFORMANCE LIMIT STATES FOR RC BEAMS AND COLUMNS

Defining the performance limit states and selecting proper damage indexes for quantifying the seismic damage state of building structures are the first important step for seismic performance evaluation. In this study, five damage levels, i.e., intact, very slightly damaged, slightly damaged, moderately damaged and severely damaged, were considered. The definitions of all damage limit states are shown in Table 1.

Table 1 Definitions of damage limit states

Damage levels	Damage description[1]	Repairing methods	Classified criteria[2, 3, 4]		
			Steel strain limit	Concrete strain limit	Deformation or force limit
Intact	The member substantially retains the elastic state. No yielding occurs. ($\omega_{res}<0.2$mm)	Repair is not needed.	f_y/E_s	0.002	$\theta\leq\theta_y$
Very slight	The member substantially retains its original strength. Yielding is possible. No crushing occurs. ($0.2\leq\omega_{res}<1$mm)	Repair is not needed in normal environment. Minor repairs may be appropriate for structures in extreme environment.	0.015	0.0033	——
Slight	Visible cracks extend. Minor crushing occurs. ($1\leq\omega_{res}<2$mm)	Injection of epoxy is needed to avoid later corrosion. No significant remedial measures are needed.	0.030	0.005	——
Moderate	Spalling of cover concrete occurs. ($2\leq\omega_{res}<4$mm)	A certain amount of repair is acceptable, but the cost should be significant less than the cost of replacement.	0.060	$0.75\varepsilon_{cu}$	
Severe	The range of concrete spalling extends. No collapse occurs.	Repair becomes no longer feasible.	0.072	ε_{cu}	$F_{res}\geq85\%F_{max}$

1. ω_{res} is the maximum residual crack width; 2. θ is the total rotation of the member, f_y and E_s are the yield strength and elastic modulus of steel reinforcement; 3. ε_{cu} is the ultimate compressive strain of concrete, and F_{res} is the residual load-carrying capacity of the member; 4. For each damage state, the minimum value of the rotation determined by the classified criteria is selected as the deformation limit.

For the damage level of "intact", the concrete compressive strain limit is defined as the strain corresponding to the peak stress of the concrete, and the steel tensile strain limit is defined as the yield strain of the steel bar. For the damage level of "very slight", the concrete compressive strain limit is defined as the strain at which the crushing begins, and the steel tensile strain limit is defined as the strain at which the maximum residual crack width exceeds 1mm, thus likely requiring repair (Priestly *et al*. 1996) and interrupting serviceability. For the damage level of slight, the concrete compressive strain limit is defined as the compressive strain at which the slight crushing of cover concrete begins, and the steel tensile strain limit is defined as the strain at which the maximum residual crack width exceeds 2mm, thus slight repairing, such as injection of the epoxy, is required to avoid later corrosion. According to ATC-40 (ATC 1996), for the damage level of "moderate", the concrete compressive strain limit is defined as 75% of the ultimate concrete compressive strain, and the steel tensile strain limit is defined as the strain at which the maximum residual crack width exceeds 4mm. The steel tensile strain of 0.06 is selected as the limit value at this damage state (Priestly *et al*. 1996; Kowalsky 2000). For the damage level of "severe" which means the post-earthquake damage state on the verge of partial or total collapse (FEMA 2000), the residual load-carrying capacity of the component shall be larger than 85% of the maximum load-carrying capacity. The compressive strain of the concrete shall not be larger than the ultimate compressive strain. The steel tensile strain must also be limited to avoid rupture or buckling while the deformation capacity is reduced due to the cyclic loading (Priestly *et al*. 1996).

CORROSION DAMAGE MODELS OF CORRODED RC BEAMS AND COLUMNS

The consequences of the steel bar corrosion can range from progressive deterioration of the RC structural member and the structure over time to the catastrophic failure. Therefore, the effects of steel bar corrosion need to be carefully assessed in the numerical model. The following aspects were considered herein:

- Steel area reduction in the longitudinal steel bars and stirrups;
- Changes in the mechanical properties of steel bars owing to the pitting corrosion;
- Equivalent changes in the strength and ductility of the concrete in compression, due to the micro cracking and the spalling of concrete induced by the bar expansion;
- Strength deterioration of the bonding between the corroded steel bars and surrounding concrete.

Steel bars

In this study, for simplicity the uniform corrosion was considered and modelled simply by reducing the cross-sectional area as well as the yield strength of reinforcement according to the work (Zhang *et al*. 2006). The reduced cross-sectional area and yield strength of corroded steel bars can be calculated according to the following equations:

$$A_D = (1-\eta)A_0 \tag{1}$$

$$f_{yk}^D = \frac{(1-1.231\eta)}{(1-\eta)} f_{yk} \tag{2}$$

Where A_D and A_0 are the reduced and initial cross-sectional area, respectively; f_{yk}^D and f_{yk} are the reduced and initial yield strength, respectively; η is the corrosion ratio.

Residual strength of corrosion damaged concrete

As suggested by Coronelli and Gambarova (2004), the effect of the concrete cracking and spalling was reflected by reducing the strength of the cover concrete. The reduced concrete strength can be calculated according to the model proposed by Vecchio and Collins (1986), as follows:

$$f_{ck}^D = \frac{f_{ck}}{1+R\varepsilon_1/\varepsilon_{co}} \tag{3}$$

Where f_{ck}^D and f_{ck} are the compressive strength of the damaged concrete and undamaged concrete, respectively; R is the coefficient related to the roughness and diameter of the steel bar, and for medium-diameter deformed bars it is taken as 0.1, as suggested by Cape (1999); ε_1 is the average tensile strain in the cracked concrete perpendicular to the direction of the applied compression; ε_{co} is the concrete strain at peak compressive strength.

Bond-slip relationship between corroded bars and surrounding concrete

Based on the bond stress-slip relationship proposed by CEB-FIP Model Code 90 (1993), the following equation was adopted to incorporate the corrosion effects:

$$\tau(s) = \beta\tau_0(s) \tag{4}$$

Where τ(s) is the bond stress between the corroded steel rebar and the surrounding concrete; τ_0(s) is the bond stress between the uncorroded steel rebar and the surrounding concrete, which is proposed by CEB-FIP Model Code 90 (1993), as shown in Figure 1; β is the normalized bond strength defined as the ratio of bond strength at certain corrosion ratio η to the original bond strength of the uncrorroded specimen. The model proposed by Bhargava *et al*. (2008) was applied to determine the normalized bond strength β, as follows:

$$\beta = \begin{cases} 1.0 & \eta \le 1.5\% \\ 1.192e^{-11.7\eta} & \eta > 1.5\% \end{cases} \tag{5}$$

The normalized bond strength β versus corrosion ratio η relationship is shown in Figure 2.

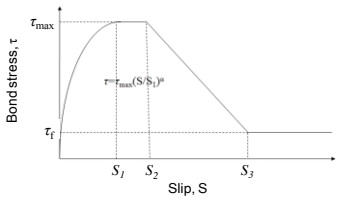

Figure 1 Bond-slip relationship for uncorroded specimen

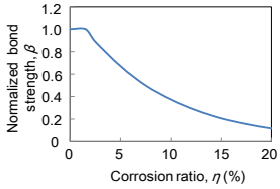

Figure 2 Normalized bond strength versus corrosion ratio relationship

FINITE ELEMENT MODEL OF CORRODED RC BEAMS AND COLUMNS

The numerical analysis of corroded RC beams and columns was conducted with the aid of ABAQUS finite element analysis program. A three-dimensional finite element model was adopted in this study. The concrete was modelled using 8-node 3D stress element (C3D8R). The concrete damage plasticity model with the constitutive relationship recommended by Chinese code for design of concrete structures (MOHURD 2010) was adopted. All stirrups were modelled using 2-node linear 3-D truss elements (T3D2) while the longitudinal reinforcement was modelled using 2-node linear beam element (B31). All the steel bars were assumed to exhibit elastic-perfectly plastic behavior. The bond between the longitudinal reinforcement and the concrete was modelled using the connector with the bond-slip relationship calculated according to Eqs 4 and 5.

Corroded RC members from three experimental studies were used herein to verify the FE models (Niu *et al*. 2004; Ma *et al*. 2012; Wang 2008).The comparison of load-displacement curves between the test and numerical

results are shown in Figure 3. It is found that the numerical results are in good agreement with the test results, which indicates that the corrosion damage model and finite element modelling technique adopted herein can accurately predict the behavior of corroded RC members. Subsequently, they can be used in the parametric study to examine the influence of various parameters on the behavior of corroded RC members.

PARAMETRIC STUDY

324 RC beams were designed according to the current Chinese code. The cross-section of the beam is a rectangle with the dimensions of 300×600 mm. For the RC beam, the main parameters considered in this paper are the corrosion ratio of the steel reinforcement η, the shear span ratio λ, and the longitudinal reinforcement characteristic value K determined by the following equation:

$$K = \frac{f_y\left(A_s - A_s^{'}\right)}{f_c b h_0 \xi_b} \tag{6}$$

Where f_y is the design yield strength of the longitudinal reinforcement; f_c is the design compressive strength of the concrete; A_s and A_s' are the area of the tensile and compressive longitudinal reinforcement, respectively; b and h_0 are the width and effective depth of the cross-section, respectively; ξ_b is the ratio of the balanced depth to the effective depth of the cross-section. The corrosion ratio of the steel reinforcement ranges from 0% to 20% at an interval of 2.5%. Four shear span ratios, i.e., 3, 4, 5 and 6, as well as nine discrete values of K ranging from 0 to 0.8, were considered. The corroded RC beam is numbered as Bη-K-λ. For example, B5-2-4 represents a beam with corrosion ratio of 5%, longitudinal reinforcement characteristic value of 0.2 and the shear span ratio of 4.

According to the current Chinese code, 954 RC columns were designed. The cross-section of the column is a rectangle with the dimensions of 450×450 mm. The corrosion ratio η of reinforced bars, axial compressive load ratio n, shear span ratio λ, volumetric stirrup ratio ρ_v and longitudinal reinforcement ratio ρ_l were considered as the main parameters for RC columns. Similar to RC beam described above, the corrosion ratio of the steel reinforcement ranges from 0% to 20% at an interval of 2.5%. Four axial compressive load ratios, i.e., 0.2, 0.4, 0.6 and 0.8, as well as three shear span ratios, i.e., 3, 4, and 5, were considered. Three levels of volumetric stirrup ratio ρ_v, i.e., 0.79% (B8@100), 1.24% (B10@100) and 1.78% (B12@100), as well as three levels of longitudinal reinforcement ratio ρ_l, i.e., 0.6% (8C14), 1.24%(8C 20) and 1.94% (8C25), were selected. The RC columns are numbered as Cη-n-λ-d_v -d_l.

The cube compression strength of original concrete was 30 MPa. The yield strength of uncorroded longitudinal reinforcement and stirrup are 400 MPa and 330 MPa, respectively. Dimensions and typical reinforcement details of the beams and columns are shown in Figure 4. The corrosion damage model and finite element modelling technique described above were adopted in the analysis. The finite element analytical model of the specimen is shown in Figure 5. The specimens are fixed at the base. For RC beams, only the horizontal load is applied at the top while for RC columns, the constant axial compressive load is applied at the top before imposing lateral load at the top.

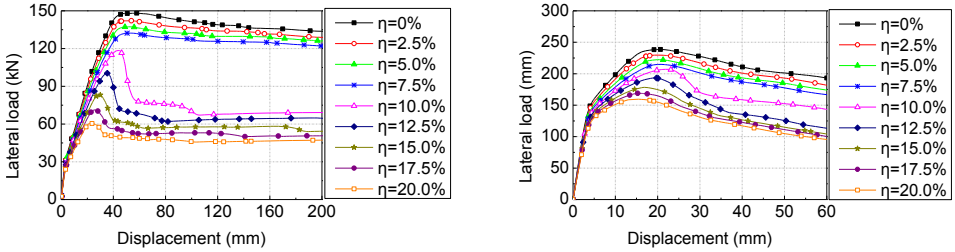
RESULTS AND DISCUSSION

Lateral load versus displacement curves

The typical lateral load versus displacement curves obtained are shown in Figure 6. It is found that the corrosion of steel reinforcement has little effect on the performance of RC members before cracking. After cracking, the lateral strength as well as the stiffness of the specimens decreases with the increase of the corrosion ratio. For the specimen with the corrosion ratio smaller than 10%, the lateral load versus displacement curve is similar to that of the original specimen. For specimens with the corrosion ratio lager than 10%, the post peak load and stiffness of the specimen drop more significantly with the increase of displacement than those of the specimen with the corrosion ratio smaller than 10%. Compared with corroded RC columns, the effect of steel reinforcement corrosion on the lateral load-displacement curves of RC beam is more pronounced.

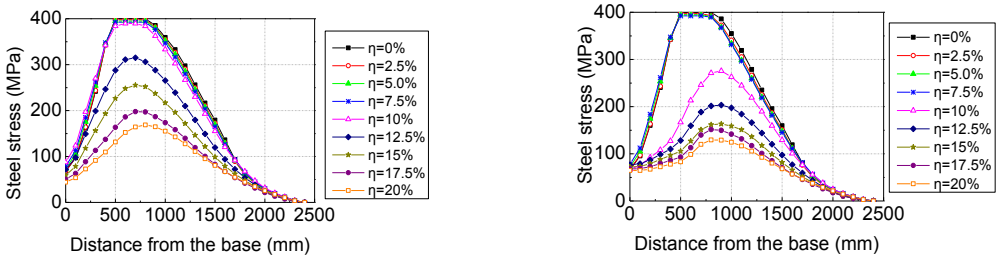


(a) Beam (Bη-5-6) (b) Column (Cη-4-4-12-20)

Figure 6 Lateral load versus displacement curves

Stress of longitudinal reinforcement

Figure 7 shows the steel stress along the tensile longitudinal reinforcement. For the specimen with the corrosion ratio smaller than 10%, the largest stress of tensile longitudinal reinforcement maintains at the corresponding yield strength at both peak load state and ultimate limit state. For the specimen with the corrosion ratio of 10%, the largest stress of tensile longitudinal steel is close to the yield strength at peak load state and drops significantly at the ultimate limit state due to the deterioration of bond strength between the reinforcement and concrete. For the specimen with the corrosion ratio larger than 10%, the bond strength between the steel reinforcement and concrete degrades rapidly, and the largest steel stress is smaller than the corresponding yield strength at both the peak load state and the ultimate limit state, which indicates that the tensile rebar is unable to reach the yield strength and the specimen fails due to the deterioration of bond between the concrete and the longitudinal reinforced bars.



(a) Peak load state (b) Ultimate limit state

Figure 7 Stress distribution along tensile longitudinal reinforcement of Column (Cη-2-4-12-20)

Parametric analysis of deformation behavior

The inelastic deformation capacity of RC members is important for earthquake-resistant design relying on the ductility. The primary deformation index considered herein is the ultimate plastic rotation over the plastic hinge length. Based on the previous studies on plastic hinge length of RC components (Bae and Bayrak 2008), the plastic hinge length l_p shall be set equal to half of the flexural depth of RC components. The ultimate plastic rotation can be obtained by subtracting the yield rotation from the ultimate rotation over the plastic hinge length. The yield rotation was defined based on the equivalent elasto-plastic energy absorption while the ultimate rotation was calculated according to the classified criteria of the "severe" damage state listed in Table 1.

Yield rotation

Figure 8 shows the yield rotation versus corrosion ratio curves of RC beams and columns. It is found that the corrosion ratio of steel reinforcement has little influence on the yield rotation of RC beams and columns with the corrosion ratio smaller than 10%. For specimens with the corrosion ratio larger than 10%, the yield rotation significantly decreases with the increase of the corrosion ratio. According to the relationship between yield rotation and corrosion ratio, a simplified model, as shown in Figure 9, was proposed to describe the deterioration characteristic of yield rotation for corroded RC beams and columns.

For RC beams, the yield rotation versus longitudinal reinforcement characteristic value curve is shown in Figure 10. It is found that for RC beams with the corrosion ratio smaller than 7.5%, the longitudinal reinforcement characteristic value K has little effect on the yield rotation, and the yield rotation slightly increases with the increase of shear span ratio. For RC beams with corrosion ratio of 20%, the yield rotation linearly increases with the increase of K, and the shear span ratio has little influence on the yield rotation.

For RC columns, the relationships of the yield rotation with the parameters, i.e., the axial compressive load ratio, the shear span ratio, the volumetric stirrup ratio and the longitudinal reinforcement area ratio, are shown in Figures 11 and 12. It is shown that the volumetric stirrup ratio, as well as the shear span ratio, has little effect on the yield rotation of corroded RC columns. The yield rotation of RC columns linearly decreases with the increase of the axial compressive load ratio and increases with the increase of longitudinal reinforcement area ratio.

(b) η=20%

Figure 12 Yield rotation versus longitudinal reinforcement area ratio curves for RC columns with different shear span ratios

For simplicity, the curvature distribution along the length of RC beams and columns was assumed to be linear before yield. The yield rotation within the plastic hinge length shall be calculated by the following equation:

$$\theta_y = \frac{\varphi_y \left(2 - l_p / l\right) l_p}{2} \tag{7}$$

Where θ_y is the yield rotation; l_p is the assumed plastic hinge length; l is the length of the component; φ_y is the yield curvature of the component. According to the work of Priestley (2003), the yield curvature φ_y shall be expressed as

$$\varphi_y = C_1 \frac{\varepsilon_y}{h} \tag{8}$$

Where C_1 is a constant depending on the type of the RC component considered, ε_y is the yield strain of the flexural reinforcement, and h is the section depth. Substituting Eq. 8 into Eq. 7, the yield rotation of the RC beams and columns shall be calculated using the following equation:

$$\theta_y = \frac{C_1 \varepsilon_y \left(2 - l_p / l\right) l_p}{2h} \tag{9}$$

As discussed previously, the statistical analysis was conducted to derive the constant C_1 for RC beams with low corrosion ratio. According to the numerical results of the corroded RC beams with corrosion ratio not larger than 7.5%, the average value of C_1 is equal to 2.84, with a standard deviation of 0.25 and a variation coefficient of 8.85%. For RC beams with the corrosion ratio of 20%, the linear relationship between the longitudinal reinforcement characteristic value K and the yield rotation was assumed in developing the expression of θ_y for simplicity. The θ_y expression as follows was proposed for corroded RC beams:

$$C_1 = \begin{cases} 2.84 & \eta \le 7.5\% \\ 1.663K + 1.164 & \eta = 20\% \end{cases} \tag{10}$$

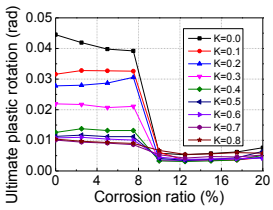
For RC beams with the corrosion ratio between 7.5% and 20%, the yield rotation can be obtained by the linear interpolation. For RC columns, the linear relationship between the parameters, i.e., the axial compressive load ratio and the longitudinal reinforcement ratio, and the yield rotation, was assumed in deriving the θ_y expression for simplicity. Least square analyses were conducted to identify the coefficient for each parameter using the numerical results of corroded RC columns. The θ_y expression as follows was proposed for corroded RC columns:

$$C_1 = \begin{cases} 2.037 - 1.66n + 94\rho_l & \eta \le 7.5\% \\ 1.027 + 44.5\rho_l & \eta = 20\% \end{cases} \tag{11}$$

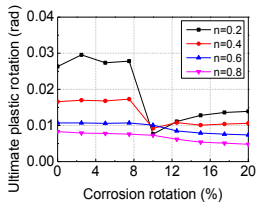
For RC columns with the corrosion ratio between 7.5% and 20%, θ_y can be obtained by the linear interpolation.

Ultimate plastic rotation

The ultimate plastic rotation versus the corrosion ratio curves of corroded RC beams and columns are shown in Figure 13. It is found that for specimens with the corrosion ratio smaller than 7.5%, the corrosion ratio has little effect on the ultimate plastic rotation. For the specimen with the corrosion ratio ranging from 7.5% to 10%, the ultimate plastic rotation drops significantly with the increase of the corrosion ratio. Serious degradation of deformation capacity appears for specimens with the corrosion ratio larger than 10%, and the corrosion ratio has little effect on the ultimate plastic rotation. According to the relationship between the ultimate plastic rotation and the corrosion ratio, a simplified model, as shown in Figure 14, was proposed to describe the deterioration characteristic of the ultimate plastic rotation for corroded RC beams and columns.



(a) Beam (Bη-K-4)



(b) Column (Cη-n-3-12-20)

Figure 13 Ultimate plastic rotation versus corrosion ratio of steel reinforcement

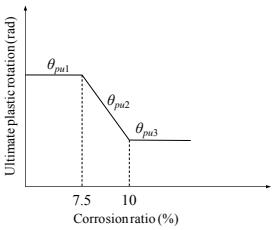


Figure 14 Model of ultimate plastic rotation versus corrosion ratio

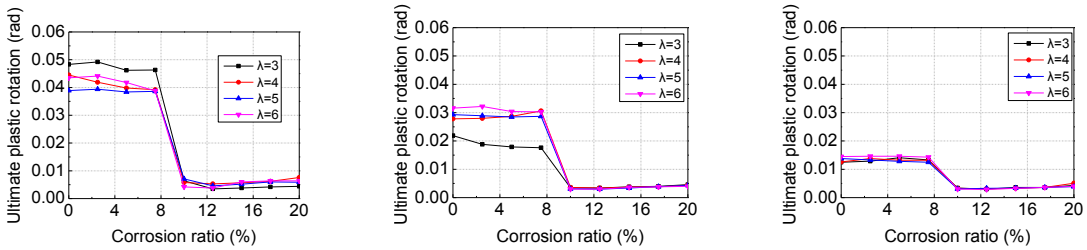
For RC beams with the corrosion ratio smaller than 7.5%, the ultimate plastic rotation decreases with the increase of longitudinal reinforcement characteristic value K, and the affecting degree increases with the increase of K, as shown in Figure 13(a). The ultimate plastic rotation of RC beams with different shear span ratios is shown in Figure 15. For RC beams with K equal to 0, the "severe" limit state was determined by the steel tensile strain, the ultimate plastic rotation decreases with the increase of the shear span ratio. For RC beams with K larger than 0.1, the concrete compressive strain governs the "severe" limit state, and the ultimate plastic rotation increases with the increase of the shear span ratio. In general, the effect of the shear span ration on the ultimate plastic rotation of RC beams with K larger than 0.4 is not significant.



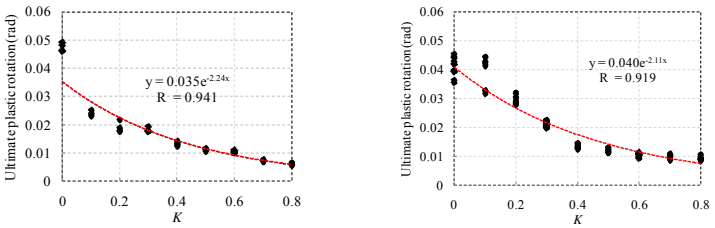
(a) K=0.0 (b) K=0.2 (c) K=0.4

Figure 15 Ultimate plastic rotations of RC beams with different shear span ratios

Based on the parametric analysis described above, the ultimate plastic rotation versus longitudinal reinforcement characteristic value curves of RC beams with the corrosion ratio smaller than 7.5% are shown in Figure 16. Exponential function was selected to describe the relationship between ultimate plastic rotation of RC beams and the longitudinal reinforcement characteristic value K. The ultimate plastic rotation of RC beams with the corrosion ratio smaller than 7.5% shall be calculated by the following equation:

$$\theta_{pu} = \begin{cases} 0.035e^{-2.24K} & \lambda = 3 \\ 0.040e^{-2.11K} & \lambda \geq 4 \end{cases} \tag{12}$$

For RC beams with corrosion ratio larger than 10%, the shear span ration, as well as K, has little effect on the ultimate plastic rotation. The distribution of ultimate plastic rotation of RC beams with corrosion ratio larger than 10% is shown in Figure 17. The average value of the ultimate plastic rotation is 0.0042, with the standard deviation of 0.000392 and the variation coefficient of 21.98%.



(a) λ=3 (b) λ≥4

Figure 16 Ultimate plastic rotation versus longitudinal reinforcement characteristic value curves (η≤7.5%)

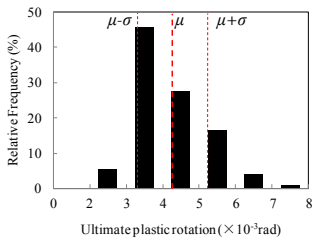


Figure 17 Distribution of ultimate plastic rotation for specimens with corrosion ratio of 20%

The ultimate plastic rotation of RC columns with different shear span ratio is shown in Figure 18. It is found that the differences in the ultimate plastic rotation of RC columns with different shear span ratios are not distinct. Figure 19 shows the ultimate plastic rotation of RC columns with different volumetric stirrup ratios. It is found that for RC columns with the corrosion ration smaller than 7.5%, the ultimate plastic rotation slightly increases with the increase of the volumetric stirrup ratio, but the effect of volumetric stirrup ratio is not significant. As shown in Figure 13(b), the ultimate plastic rotation significantly decreases with the increase of axial compressive load ratio for RC columns with the corrosion ratio smaller than 10%. While for RC columns with the corrosion ratio larger than 10%, the influence of axial compressive load ratio is reduced. Figure 20 shows the relationship between the average ultimate plastic rotation and the axial compressive load ratio of RC columns. With the increase of axial compressive load ratio, the ultimate plastic rotation decreases exponentially. Average ultimate plastic rotation versus longitudinal reinforcement ratio curves are shown in Figure 21. For RC columns with the corrosion ratio smaller than 7.5%, the ultimate plastic rotation linearly increases with the increase of longitudinal reinforcement ratio. For RC columns with the corrosion ratio larger than 10%, the effect of the longitudinal reinforcement ratio on the ultimate plastic rotation is not significant.

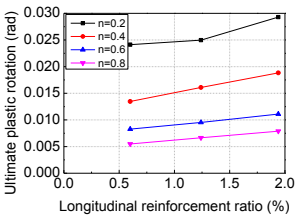
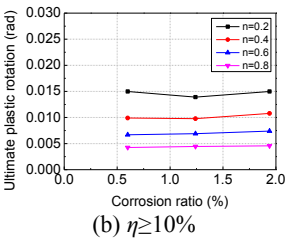
(b) $\eta \geq 10\%$

Figure 20 Average ultimate plastic rotation versus axial compressive load ratio curves of RC columns



(a) $\eta \leq 7.5\%$



(b) $\eta \geq 10\%$

Figure 21 Average ultimate plastic rotation versus longitudinal reinforcement ratio curves of RC columns

Based on the parametric analysis results discussed above, the following function was assumed to describe the relationship between ultimate plastic rotation of RC columns with the main parameters, i.e., axial compressive load ratio and longitudinal reinforcement ratio:

$$\theta_{pu} = \begin{cases} (a_1\rho_l + b_1)\ e^{-c_1 n} & \eta \leq 7.5\% \\ a_2 e^{-c_2 n} & \eta \geq 10\% \end{cases} \quad (13)$$

Where a_1, b_1, c_1, a_2 and c_2 are the regression coefficients determined by least squares analyses using the numerical results of corroded RC columns. The expression shown in following equation was obtained for the ultimate plastic rotation of RC columns with the corrosion ratio smaller than 7.5% or larger than 10%:

$$\theta_{pu} = \begin{cases} (0.9\rho_l + 0.029)\ e^{-2.31n} & \eta \leq 7.5\% \\ 0.022e^{-1.97n} & \eta \geq 10\% \end{cases} \quad (14)$$

For RC columns with the corrosion ratio between 7.5% and 10%, the ultimate plastic rotation can be obtained by the linear interpolation.

Deformation limits corresponding to various damage states

Based on the numerical results of corroded RC beams and columns, the deformation limits corresponding to various damage states were determined according to the criteria listed in Table 1. The proportional factor d_i is defined as the ratio of the plastic rotation corresponding to the i^{th} damage state to the ultimate plastic rotation. For the 'intact' state, the proportional factor d_1 is defined as the ratio of the total rotation to the yield rotation. The distributions of deformation proportional factors d_i for individual damage state are shown in Figures 22 and 23. The statistical characteristic values of each deformation proportional factor d_i are listed in Table 2.

Table 2 Statistical characteristics of deformation proportional factor

Component	Damage state	d_i	Statistical characteristics for d_i[1]				
			m	m-σ	m+σ	$P_{di\in[m-\sigma, m+\sigma]}$	$P_{di\geq m-\sigma}$
RC beam	Intact	θ_1/θ_y	0.87	0.75	0.99	50.7%	80%
	Very slight	θ_{p2}/θ_{pu}	0.06	0.05	0.07	67.3%	85.5%
	Slight	$\theta_{p3}\theta_{pu}$	0.45	0.35	0.55	81.7%	84.5%

	Moderate	$\theta_{p4}\theta_{pu}$	0.76	0.66	0.85	67.8%	84.3%
	Severe	$\theta_{p5}\theta_{pu}$	1.0	-	-	-	-
RC column	Intact	θ_1/θ_y	0.96	0.89	1.04	84.8%	84.8%
	Very slight	θ_{p2}/θ_{pu}	0.11	0.08	0.15	60.6%	76.9%
	Slight	$\theta_{p3}\theta_{pu}$	0.41	0.35	0.48	69.8%	84.4%
	Moderate	$\theta_{p4}\theta_{pu}$	0.70	0.65	0.84	68.3%	86.5%
	Severe	$\theta_{p5}\theta_{pu}$	1.0	-	-	-	-

1. m is the mean value of the proportional factor d_i, σ is the standard deviation, and P is the distribution probability.

As shown in Figures 22-23 and Table 2, it is observed that the dispersion of the deformation proportional ratios corresponding to individual damage states is small. The probability of the proportional ratios exceeding the mean m minus one standard deviation σ is larger than 80% for most of the damage states. Accordingly, the m-σ bound of deformation proportional ratios d_i is suggested to be used as the deformation proportional ratio limits in seismic evaluation and performance-based seismic design of RC structures.

CONCLUSIONS

To quantify the seismic damage levels of building structures, the material strain-based criteria to classify the performance limit states of RC beams and columns were proposed in this study. Numerical analysis of corroded RC beams and columns in a wide range of design parameters was performed with the aid of ABAQUS finite element analytical program to evaluate the deformation behavior of corroded RC members. Based on the numerical results, the expressions for yield rotation and ultimate plastic rotation of corroded RC beams and columns were derived. Furthermore, statistical characteristic values of deformation limits corresponding to various damage states were derived according to numerical results. The research results can be utilized for life-cycle oriented seismic design and seismic performance evaluation of RC structures.

ABSTRACT

In reliability-based durability design of reinforced concrete (RC) structures, the depassivation of reinforcing steels is often taken as the durability limit state, and the target reliability index is a key parameter controlling the long-term durability performance of RC members. This study investigates the impact of target reliability of durability design in design phase on the life-cycle performance and the maintenance cost of RC structures. For this purpose, a chloride diffusion model for steel depassivation of RC members is firstly established; and then the cost models for maintenance of RC beam members are proposed. Based on the detailed section design and the durability limit state of steel depassivation, Monte-Carlo simulation is used to calculate the reliability index for the durability design of RC beam members; and then according to the defined maintenance inventions and associated costs, the maintenance costs for the whole service life are evaluated for different durability reliability indices. Finally, the impact of target reliability of durability design on the deterioration process and the maintenance cost is discussed.

KEYWORDS

Durability design; target reliability; maintenance cost; reinforced concrete members; chloride environment.

INTRODUCTION

Maintenance is essential to ensure the expected service life of reinforced concrete (RC) structures, especially for port structures which are subjected to the attack of chloride ions in marine environment. The maintenance cost of a port structure depends on the structural deterioration rate, allowable limit state intervention techniques, maintenance schemes and the generated user costs. Existing studies have investigated the impact of maintenance interval, discount rate, maintenance schemes and allowable limit states on maintenance cost (Val, 2005; Kendall et al., 2008; Chiu et al, 2010). And cost-based methods, e.g. life cycle cost analysis, have been extensively applied to optimize the maintenance works for RC structures (Singh and Tiong 2005; Bucher and Frangopol, 2006; Li et al. 2009). In reliability-based durability design of RC structures, the depassivation of reinforcing steels is often taken as the durability limit state, and the target reliability level has important impact on the deterioration rate, thus also on the maintenance cost. In Chinese code for durability design of RC elements, the target reliability of embedded steel bars remaining passivated is stipulated as 1.3 (CCES, 2005), while in European code the target reliability is 1.5 (Duracrete, 1998). Theoretically, the determination of target reliability should distinguish the expected service life of the structure, which could be done in the context of life-cycle cost, however up to now, no research work has been performed on the life-based durability design of reinforce concrete structures.

This paper investigates the impact of target reliability on the maintenance cost of RC structure of a marine port with a design service life of 30 years. The port of container wharf was built in 1998 and located in Guangzhou, China. The structure of wharf is a RC beam-slab system supported by high driven piles. The annual average temperature is between 22.3-23.1ºC with most elevated temperature as 28.4-28.8 ºC (July) and lowest temperature as 14.8-15.9 ºC (January). The annual average humidity is between 77-80% with important seasonal variation, and the seasonal humidity can reach 100% (spring and summer) and drop to 10% (winter). The main durability process for the RC structural members is identified as the chloride-induced corrosion of reinforcing steel bars. In this paper, the deterioration models and cost models are first established for the RC beams in the wharf. And then, the influence of target reliability of durability design for RC structures is investigated for its

impact on the deterioration process of RC elements as well as the resulted maintenance costs. As a result, the optimized target reliability is discussed for the durability design of RC elements.

MODELS

Deterioration of RC members

The control process for the deterioration of RC members is chloride-induced corrosion of the embedded steel bars. The durability limit state is defined as the steel de-passivation, i.e. the external chloride ions penetrate into the concrete and accumulate at the steel surface, to a critical concentration high enough to initiate the steel corrosion. The analytical solution of Fick's second law is usually retained as engineering model (DuraCrete, 1998; fib, 2006), and the design equation for corrosion process can be expressed as:

$$G = \left\{ C_0 + \left(C_S - C_0\right)\left[1 - erf\left(\frac{x}{2\sqrt{D_{\mathrm{Cl}}(t)\cdot t}}\right)\right]\right\} - C_{Cr} \geq 0 \tag{1}$$

in which C_0 is the initial chloride content in the concrete; C_S is a constant chloride concentration imposed on the surface; x is the thickness of concrete cover; D_{Cl} is the *apparent* chloride diffusion coefficient in concrete and *erf* is the mathematical error function. This apparent diffusion coefficient is found to be time-dependent (Bamforth, 1999), and a power law is recommended for its ageing behavior (Mangat and Molloy, 1994),

$$D_{\mathrm{Cl}}(t) = D_{\mathrm{Cl}}^{0}\left(\frac{t_0}{t}\right)^{a} \tag{2}$$

with D_{Cl}^{0} stands for the diffusion coefficient at concrete age t_0, a for the exponential coefficient. In the calculation of D_{Cl}, t is taken as 30 years as $t > 30$ years

Cost models

The maintenance cost of a RC element during its service life can be is expressed as

$$C_m = \sum_{i=1}^{n}\left(\frac{C_{r,i}}{(1+r)^{t_i}} + \frac{C_{u,i}}{(1+r)^{t_i}}\right) \tag{3}$$

in which C_m is the total maintenance cost; $C_{r,i}$ is the cost of the ith maintenance intervention; $C_{u,i}$ stands for the user cost of ith maintenance by possible disturbance and stoppage of berth service; n is the number of maintenances during service life and t_i is the time (year) of the ith maintenance; r is the discount rate of currency. The discount rate r is determined by the social discount rate and the annual changing rate of producer price index (PPI). According to Cady (1983), the discount rate is assumed to adopt a step function:

$$r = \begin{cases} 2.0\% & t_i = 0 \sim 30 \text{ years} \\ 2.7\% & t_i = 31 \sim 60 \text{ years} \\ 3.3\% & t_i = 61 \sim 90 \text{ years} \\ 4.0\% & t_i > 90 \text{ years} \end{cases} \tag{4}$$

DETERIORATION AND MAINTENANCE

The exposure zones of RC elements in marine environment are classified as immerged zone, tidal zone, splash zone and atmospheric zone, as seen in Figure 1. In the paper, for purpose of simplicity, the maintenance plan concerns cross beams only. The design parameters of the cross sections are in Table 1.

The function in Eq.1 is used to calculate the failure probability of RC elements under chloride action. The basic parameters are C_0, C_S, C_{Cr}, D and a. These parameters all depend on concrete material composition and have statistical properties. Their statistical properties are obtained by on-site survey of similar port structures in Guangzhou and referring to durability standards (CCES 2005; fib 2006), and listed in Table 1.

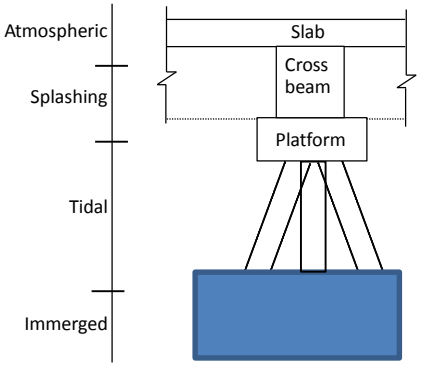

Figure1 Vertical view and exposure zone of RC elements in the wharf

Table 1 Design values and statistics of durability parameters

Design parameters			
Dimension (m)	Concrete	D_0 (10^{-12}m^2/s)	Concrete Cover (mm)
8.5×1.4×2.0	C45	4.5	70
Statistics of parameters in deterioration model			
Parameter	Distribution	Mean Value	Coefficient of Variation
C_0 (%binder)	Lognormal	0.06	0.1
C_S (%binder)	Lognormal	4.5	0.15
x (mm)	Normal	65, 70, 75	0.1
C_{Cr} (%binder)	Lognormal	0.45	0.2
D (10^{-12}m^2/s)	Lognormal	According to Eq.(2)	0.2
a (-)	Lognormal	0.4	0.1

Monte-Carlo simulation is used to obtain the failure probability of Eq. 1. The total number of samples is 100,000. The failure probability of the cross beam is shown in Figure 2, which increases as the service age grows.

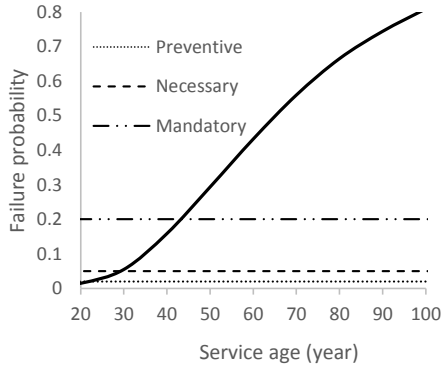

Figure 2 Failure probability of cross beam as the increase of service age

In practice, the maintenance intervention methods are decided based on the deterioration condition of RC members. The adopted intervention techniques depend strongly on the damage condition of members, which is dominantly affected by the corrosion extent of steel reinforcing bars, thus the corrosion extent of steel bars determines majorly the maintenance cost of RC members. Recognizing this, in this paper, three levels of intervention levels, named “preventive”, “necessary” and “mandatory” represented by failure probability of steel bar de-passivation, are defined in the maintenance planning of RC elements in the wharf, as seen in Table 2. The failure probabilities are 2%, 5% and 20% respectively corresponding to the “preventive”, “necessary” and “mandatory” maintenance levels, which are also shown in Figure 2. Table 2 lists the costs for the maintenance techniques considered in this study and the corresponding impact on port regular service of the three intervention levels. The maintenance cost is given as a “relative cost” which is calculated in terms of the price of new

member including the design cost, material cost and construction cost. The user daily cost is estimated on the basis of the income of berths in last 10 years in this port, which is roughly 0.009 of the price of the new structure.

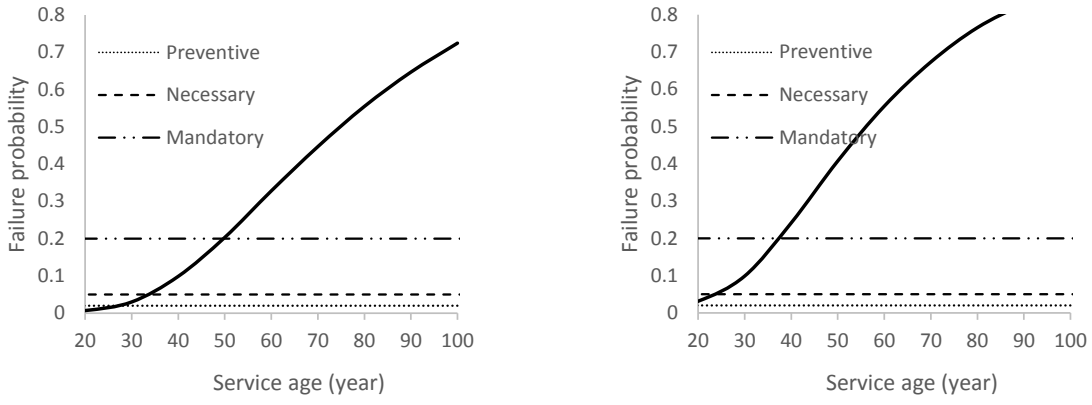
Table 2 Definition of 3 interventions

Maintenance level	Operations	Intervention cost	Service disturbance
Preventive, $P_f = 2\%$	Chloride extraction	0.88	Almost no disturbance
Necessary, $P_f = 5\%$	Chloride extraction & Surface treatment	1.14	Limited disturbance
Mandatory, $P_f = 20\%$	Cover reconstruction & Steel supplement	2.10	Close for 90 days.

According to the deterioration process shown in Figure 2, suppose that the port structure is expected to work for 100 years, the intervention times for the "preventive" level are 21year, 42year, 63year and 84year, respectively; for "necessary" level they are 29 year, 58year and 87year; for "mandatory" level they are 44year and 88year. With the intervention costs in Table 2, the maintenance costs for difference intervention levels are obtained. They are 1.04, 0.95 and 1.12 for the 3 intervention levels respectively. From the cost analysis, it can be seen that "necessary" maintenance achieves the lowest cost; "preventive" maintenance generates higher costs because of the very frequent operations; "mandatory" maintenance generates higher costs due to the associated high user costs caused by closed service during the heavy maintenance operations.

IMPACT OF TARGET RELIABILITY

The cross beams in the considered port structure has a reliability level of $\beta = 1.6$ (failure probability of 5.5%) for durability for design life of 30 years. If the target reliability increases to 1.9 (failure probability of 3%) or decreases to 1.3 (failure probability of 10%), with concrete diffusion coefficient remaining unchanged, the concrete cover thickness needs to increase to 75mm, or decreases to 65mm, respectively. For these two cases, the failure probabilities of the cross beam are obtained through Monte-Carlo simulation and shown in Figure 3.



(a) $\beta = 1.9$ (b) $\beta = 1.3$

Figure 3 Failure probability of cross beam with changed target reliability level

With the deterioration process in Figure 3 and the maintenance costs in Table 2, the maintenance intervals and costs for the three intervention levels are determined and given in Table 3. It can be seen that the "necessary" maintenance always achieves the lowest cost, which indicates that the optimum maintenance plan should be made referring to the "necessary" maintenance level. To investigate the impact of target reliability on the maintenance cost, more reliability indices are considered, and the associated maintenance costs are plot in Figure4. It is clearly seen that the maintenance cost decreases with the increase of durability reliability; in the range of durability reliability index being smaller than 1.6, the decrease of maintenance cost is relatively rapid, while in the range of durability reliability index being larger than 2.0, the decrease of maintenance cost is relatively slow. Therefore, it can be concluded that the optimum target reliability index should lie between 1.6 and 2.0, and the determination of it should refer to the increase in the construction cost as the target reliability index becomes larger.

Table 3 Maintenance levels and costs

Target reliability	Maintenance Level	Maintenance Interval	Intervention cost	User cost	Maintenance
1.3	Preventive	17	1.36	0	1.36
	Necessary	23	1.21	0	1.21
	Mandatory	37	0.97	0.38	1.35
1.6	Preventive	21	1.04	0	1.04
	Necessary	29	0.95	0	0.95
	Mandatory	44	0.81	0.31	1.12
1.9	Preventive	26	0.82	0	0.82
	Necessary	33	0.63	0	0.63
	Mandatory	49	0.50	0.18	0.68

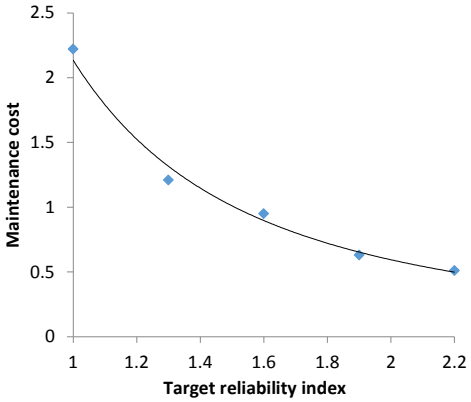


Figure 4 Dependence of maintenance cost on target reliability index

CONCLUSIONS

This paper establishes the deterioration model and maintenance cost model for the life-cycle cost analysis of RC elements in marine environments. Through Monte-Carlo simulations, taking the de-passivation of embedded reinforcing steel bars as durability limit state, the cost analyses for different durability reliabilities and maintenance levels are performed. The results show that the "necessary" maintenance, with failure probability of 5% for design life of 30 years as intervention threshold, always achieves the optimized maintenance cost; the maintenance cost decreases as the durability reliability becomes larger, but the optimum target reliability index lie between 1.6 and 2.0, and the determination of it needs to consider the change in the construction cost.

ABSTRACT

Fly ash has been increasingly used in concrete structures due to both environmental and technical benefits. Despite significant past research, our understanding of thermal and physical properties of fly ash mortar and concrete remains incomplete and thus needs further investigation. This paper presents results of a study into important fundamental thermal and physical properties of both fly ash mortar and fly ash concrete. Replacement levels of Portland cement by fly ash investigated were30%, 50% and 60% by mass. In cement-fly ash mortar tests, increasing fly ash content was found to delay setting times, decrease both compressive and flexural strengths and reduce hydration heat. The effect of fly ash on hydration heat evolution of cement binder was quantitatively analysed. The obtained reduction coefficient (k) would allow reasonable prediction of temperature rise in concrete structures, which is of particular interest for mass concrete construction. In cement-fly ash concrete tests, thermal properties, including thermal diffusivity, conductivity and specific heat, were also measured and reported. There also appeared a linear relationship between compressive and flexural strengths of concrete incorporating up to 60% fly ash by mass. In addition, the observed effect of fly ash on ultimate tensile strain, static elasticity modulus and drying shrinkage of concrete was also reported.

KEYWORDS

Fly ash, Portland cement, mortar, concrete, thermal and physical properties, reduction coefficient.

INTRODUCION

As a replacement material for Portland cement or fine aggregate, fly ash (FA) has been widely used in the production of cement-based materials (Turhan Bilir *et al*., 2015; Irshad Ali 2015). Using fly ash to replace part of Portland cement can greatly improve the workability and durability, and also significantly enhance fire resistance of concrete (Felipe Rivera *et al*., 2015; Hamdy E. *et al*., 2012). Importantly, such utilization of fly ash also has significant environmental benefits, the major of which include (O. Kayali 2008): (a) Reducing the carbon footprint in concrete production; (b) Helping to conserve the natural and scarce materials of coarse aggregates and sand; (c) recycling fly ash produced from coal-fired power plants, which is otherwise landfilled. In recent years, the use of fly ash in concrete at high percentages beyond the 30% level commonly adopted before has been studied extensively (M.J. McCarthy *et al*., 2005). The practicality and suitability of cement-based materials containing high proportion replacement of up to 80% by mass of cement by fly ash have been examined (Obada Kayali *et al*., 2013; M.S. Khan *et al*., 2015). The influence of different replacement levels of fly ash on fundamental concrete properties has been investigated widely, including physical properties

(Natalia I.V. *et al*., 2015; Erhan Guneyisi *et al*., 2014; Khuito Murumi *et al*., 2015; P. Chindaprasirt *et al*., 2004) and hydration properties (Cengiz Duran Atis 2002; L. Lam *et al*., 2000; A. Palomo *et al*. 2007; B.W. Langan *et al*. 2007). Until now, fly ash has been a common material mixed in self-compacting concrete (SCC) (N. Bouzoubaa *et al*. 2001; W. Wongkeo *et al*. 2014), roller compressive concrete (RCC) (Cengiz Duran Atis 2005) and other mass concrete (Anton K. S. *et al*. 2014).

Despite such significant past research effort, several key aspects still require further investigation: Our current understanding of the effect of fly ash on hydration heat evolution is not sufficient. Most researchers only studied the effect of fly ash on hydration heat by testing hydration products of cement-fly ash (CFA) binder (F. Puertas *et al*. 2000; S.H. Liu *et al*. 2014), but they cannot quantitatively describe the influence of fly ash on hydration heat of cement-based materials. Besides, the influence of fly ash on thermal properties has been studied by only few researchers (D.P. Bentz *et al*. 2010). With the usage of fly ash increasing in mass concrete production, thermal properties of concrete containing large volume of fly ash are increasingly of great interest. In this paper, both CFA mortar and concrete tests were designed and tested. A wide range of properties were investigated, which aimed at providing a more comprehensive knowledge of cement-based materials containing fly ash. The mortar tests mainly studied the effect of fly ash on the setting time and hydration heat evolution, while the concrete tests focused on the influence of fly ash on thermal and mechanical performance of resulting concrete. Based on the measured hydration heat of mortars, the reduction coefficient of fly ash on the hydration heat evolution can be determined, effectively allowing prediction of the adiabatic temperature rise of concrete structures. Different replacement levels of Portland cement by fly ash (30%, 50% and 60%, by mass) have been investigated. In addition to thermal properties, such other important physical properties of CFA concrete as compressive and flexural strengths, static elasticity modulus, autogenous deformation and drying shrinkage, were also studied and reported.

MATERIALS

The ordinary Portland cement (OPC) and fly ash (FA) used in the study meet the relevant Chinese National Standards (GB 175-2007) and (GB DL/T5055-2007). Main chemical proportions of FA and OPC are listed in Table 1. The density of FA and OPC is 2510kg/m^3 and 3160kg/m^3 respectively. Particle size distribution of both OPC and FA obtained by laser grain size analyzer, are shown in Figure 1(a). In the figure, FA has particle size of mainly between 0.1μm and 50.0μm while OPC's particles are mostly between 0.5μm and 100.0μm, which denotes that FA is finer than OPC. Figure 1(b) shows the cumulative percentage distribution of sieve residue of sand used in the study. It can be seen from Figure 1(b) that most of sand particles' diameter is in the interval between 0mm and 5mm.

Table 1 Chemical proportions of materials (by mass, %)

Materials	SiO_2	Fe_2O_3	Al_2O_3	CaO	MgO	K_2O	Na_2O	SO_3	Loss	Density (kg/m^3)
FA	58.24	8.62	24.80	2.66	1.96	0.82	0.15	0.31	0.78	2510
OPC	21.68	5.03	4.78	58.74	4.02	0.50	0.16	2.55	1.66	3160

CEMENT-FLY ASH MORTAR

In order to study the influence of FA on hydration and physical properties of cement-fly ash (CFA) mortar, a series of mixes with different replacement level of OPC by FA ranging between 0 and 60% by mass were designed (Table 2). The contents of total binder, water and sand were kept constant for all CFA mortar mixes and were 450g, 225g and 1350g respectively. The water-to-binder ratio by mass was thus 0.5 for all mortar mixes.

Table 2 Mix proportion of cement-fly ash mortar

MIX	Percentage of FA (by mass, %)	w/b	Materials (*g*)			
			OPC	FA	Sand	Water
CFA-1	0	0.50	450	0	1350	225
CFA-2	30	0.50	315	135	1350	225
CFA-3	50	0.50	225	225	1350	225
CFA-4	60	0.50	180	270	1350	225

Physical properties of cement-fly ash mortar

The initial and final setting times of CFA binder and the flow-ability of CFA mortar were tested in accordance with GB/T50146-2014. The results of both tests are reported in Table 3. It is clear evidenced from Table 3 that the higher the percentage of FA, the longer both the initial and final setting times. This is mainly due to the

pozzolanic nature of FA, which requires calcium hydroxide from hydration of OPC for its hydration (Neville A.M. *et al*. 2008). The flow-ability, however, does not seem to vary with the FA content.

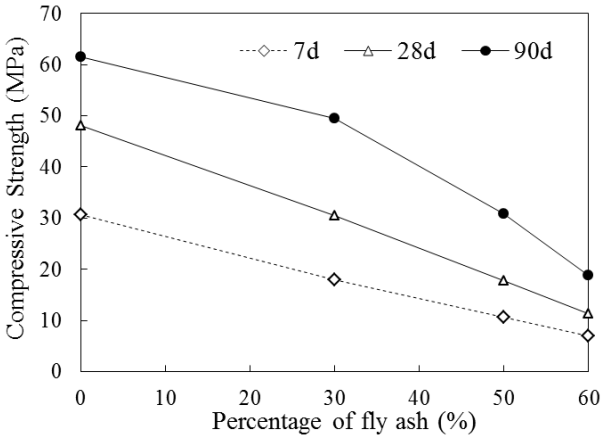
Table 3 Setting times and flow-ability

Percentage of FA (by mass, %)	Setting Time (hour: min)		Flow-ability (mm)
	Initial Setting	Final Setting	
0	3:03	4:30	135.3
30	4:44	5:39	135.2
50	4:55	7:31	135.5
60	5:49	7:48	135.0

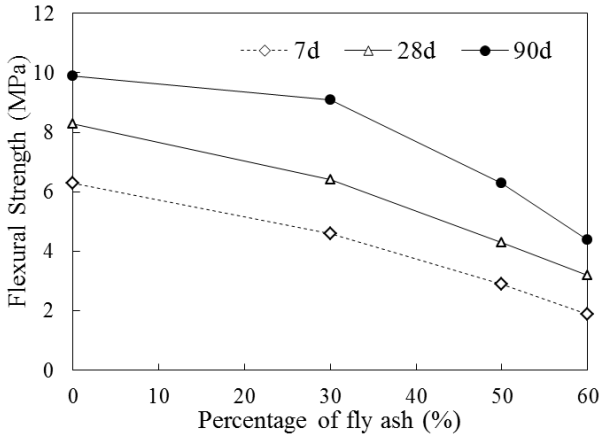
The compressive and flexural strengths of CFA mortar were also tested in accordance with GB/T17671-1999. The obtained test results are given in Table 4. The variation of strengths versus the replacement percentage of FA for OPC is plotted in Figure 2. As shown in Table 4, both compressive and flexural strengths are found to increase over time. Also, increased percentage of FA corresponds to a reduction in the strength (Figure 2), indicating that using FA to partially replace OPC is adverse for improving strength of cement-based materials. Such reduction is particularly much greater for the 90-day strengths when the percentage of FA is higher than 30%.

Table 4 Compressive and flexural strengths of mortar

Mix	Compressive Strength (MPa)			Flexural Strength (MPa)		
	7d	28d	90d	7d	28d	90d
CFA-1	30.6	48.1	61.5	6.3	8.3	9.9
CFA-2	18.0	30.5	49.5	4.6	6.4	9.1
CFA-3	10.7	17.7	30.9	2.9	4.3	6.3
CFA-4	7.0	11.3	18.9	1.9	3.2	4.4



(a)



(b)

Figure 2 Variation of strengths with fly ash content: (a) Compressive strength and (b) Flexural strength

According to DL/T5150-2001, drying shrinkage tests of CFA mortar were performed in a condition of constant temperature and humidity, and the obtained tests results are shown in Figure 3. As expected, for each mix, the measured drying shrinkage increases rapidly during the first 20 days or so. After that, the rising rate becomes small and tends to be stable. Drying shrinkage is also observed to decrease with increased FA percentage up to about 50% replacement, above which drying shrinkage seems essentially unchanged. With the replacement level of FA increasing from 0 to 50%, the average drying shrinkage value declines rapidly, denoting that using FA as a partial replacement for OPC is beneficial for restraining drying shrinkage.

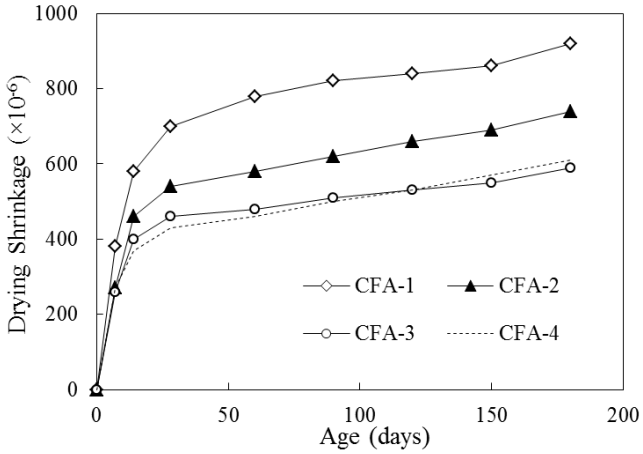


Figure 3 Drying shrinkage of cement-fly ash mortar

Effect of fly ash on hydration heat evolution

In addition to the influence of FA on physical properties, improved knowledge of the effect of FA on hydration heat of cement binder is also of significant interest. Hydration heat at different ages (from 1 to 7 days) was tested in a 20mL ampere bottle with the initial hydration temperature of 20℃. The measured data of hydration heat of CFA-1, 2, 3 and 4, is shown in Figure 4. It clearly illustrates that the higher hydration heat of CFA-1 compared to that of CFA-2, which is in turns higher than that of CFA-3, and the hydration heat of CFA-4 is the lowest. This denotes that increasing the replacement percentage of FA can significantly reduce the heat evolution of CFA binder. Also, it can be observed that the average rising rate of hydration heat becomes smaller

as the percentage of FA increases.

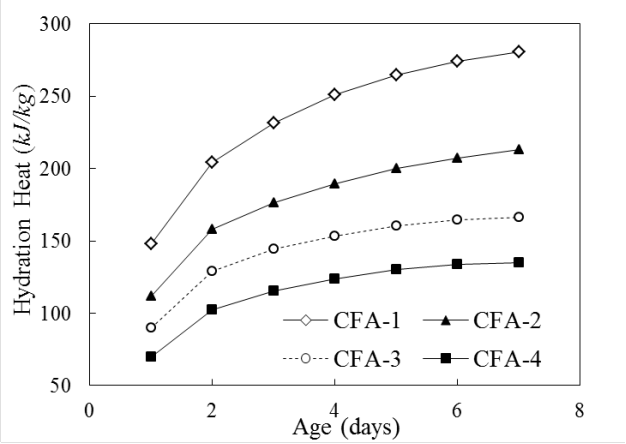

Figure 4 Hydration heat

To quantitatively analyze the reduction effect of fly ash on hydration heat evolution, a calculation equation of adiabatic temperature rise of mortar put forward by Bofang Zhu (2012) was quoted. The calculation equation can be shown as

$$\theta(\tau) = \frac{Q(\tau)(W + kF)}{c\rho} = \frac{Q_b(\tau)W_b}{c\rho} \tag{1}$$

Where: $Q(\tau)$ is the hydration heat of OPC, W is the content of OPC, k is a reduction coefficient, F is the content of FA, c is the average specific heat, $Q_b(\tau)$ is the hydration heat of CFA binder, W_b is the content of CFA binder.

Based on Eq. 1, the reduction coefficient of FA on hydration heat (k) can be expressed as

$$k = \frac{Q_b(\tau)W_b}{Q(\tau)F} - \frac{W}{F} \tag{2}$$

Combined Eq. 2 and the test data of hydration heat reported in Figure 4, the reduction coefficient k can be confirmed, and the calculation results of k are plotted in Figure 5. The obtained reduction coefficient k is found to vary between 0.12 and 0.27. For each level of fly ash content, the reduction coefficient initially increases, reaching a peak at the age of about 2 days before gradually decreasing over time. However, there is no clear relationship between the k coefficient and fly ash percentage. The average value of the reduction coefficient k peaks at CFA-3 by 0.22 while the lowest value occurs at CFA-4 by 0.15.

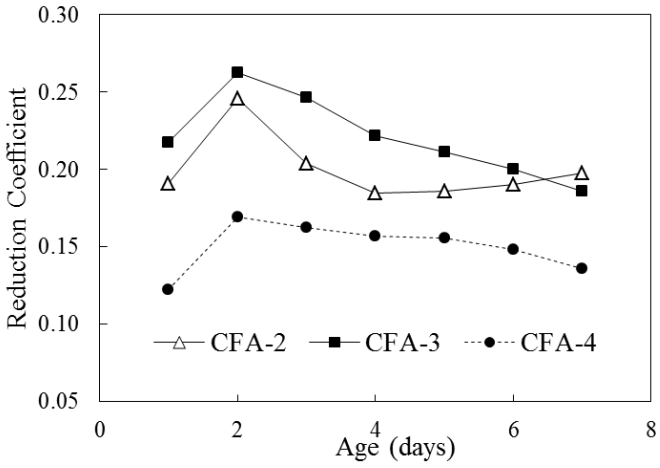

Figure 5 Reduction coefficient of fly ash on hydration heat evolution

CEMENT-FLY ASH CONCRETE

Concrete mixes with different replacement level of FA for OPC (30%, 50% and 60%, by mass), were designed (Table 5) and used to investigate the influence of FA on CFA concrete. To correspond with CFA mortar tests, the ratio of water-to-binder (*w/b*) was still kept at 1:2 by mass.

Table 5 Mixture compositions of cement-fly ash concrete

Mix	Percentage of FA (%)	w/b	Main materials (kg/m^3)				
			OPC	FA	Sand	Aggregate	Water
C-1	30	0.50	105	45	808.5	1458.2	75
C-2	50	0.50	75	75	808.5	1458.2	75
C-3	60	0.50	60	90	808.5	1458.2	75

Thermal properties

Relevant thermal parameters of cement-fly ash concrete were tested on the basis of DL/T5150-2001, and the obtained tests results are reported in Table 6. As shown in Table 6, an increase in percentage of FA results in a small decrease in thermal conductivity and linear expansion coefficient but only a relatively modest gain in Poisson's ratio. Overall, these thermal parameters listed in the table were little influenced by the increase of replacement percentage of FA. The obtained test data of adiabatic temperature rise of concrete was plotted in Figure 6. It can be observed from the figure that the increase rate of adiabatic temperature rise of C-1 is the fastest while the increase rate of C-3 is the lowest. The value of adiabatic temperature rise of C-1 at the age of 15 days is approximate 20.75℃, which is higher than the temperature of C-2 (19.89℃) and C-3 (19.42℃). This is also consistent with the hydration heat evolution measured for cement-fly ash mortar, as presented in Figure 4.

Table 6 Main thermal properties of concrete

Properties	C-1	C-2	C-3
Poisson's ratio	0.181	0.184	0.185
Thermal diffusivity (m^2/h)	0.0039	0.0041	0.0041
Thermal conductivity ($kJ/(mh℃)$)	9.687	9.667	9.619
Average specific heat ($kJ/(kg℃)$)	1.006	0.954	0.951
Linear expansion coefficient ($10^{-6}/℃$)	7.20	7.01	6.757

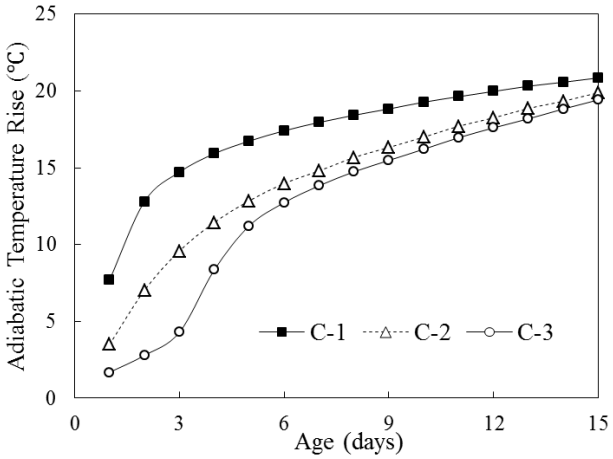

Figure 6 Adiabatic temperature rise of cement-fly ash concrete

Physical properties

Test results of compressive strength and flexural strength of CFA concrete based on DL/T5150-2001 were shown in Table 7. It is found that compressive strength and flexural strength generally increase over time while the both strengths decrease as the replacement percentage of FA rises. The relationship between the compressive strength and the flexural strength is plotted in Figure 7. The experimental results were compared to the analytical model given by American Concrete Institute (shown as Eq. 3) (ACI, 2005; Mohammad Soleymani A. *et al*. 2013). It is clearly observed that the ACI analytical line cannot be used to describe the relationship between compressive strength and flexural strength in cement-fly ash concrete studied. However, it is found that the relationship similarly meets a linear variation, which can be expressed by a linear formula as: $f_c=11.402f_\tau+3.3348$ (the square error is about 0.949).

$$f_\tau = 0.62\sqrt{f_c} \tag{3}$$

Where, f_τ is the flexural strength and f_c is the compressive strength.

Table 7 Strength properties of concrete

Mix	Compressive Strength (MPa)				Flexural Strength (MPa)			
	7d	28d	90d	180d	7d	28d	90d	180d
C-1	20.1	29.6	42.2	-	1.44	1.99	3.07	-
C-2	13.5	20.3	28.7	35.5	0.89	1.60	2.24	3.19
C-3	11.0	19.7	28.3	35.2	0.74	1.48	2.21	2.85

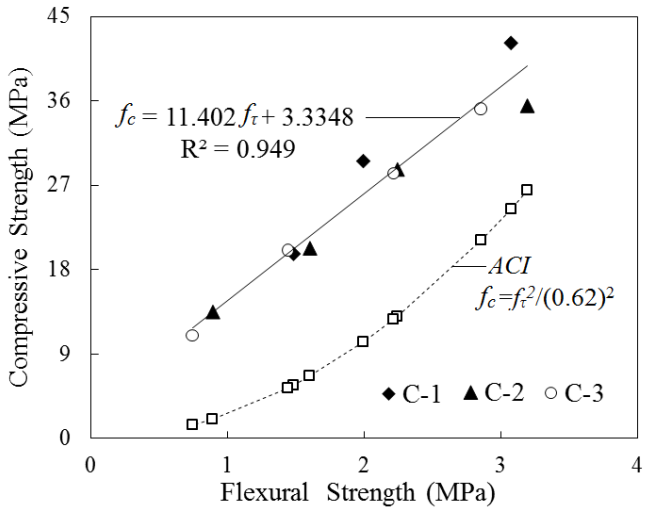

Figure 7 Relationship between compressive strength and flexural strength

Table 8 reports the effect of FA on the limiting extended value and static elasticity modulus. Both the limiting extended value test and the static elasticity modulus test were carried out, complying with China Standard DL/T5150-2001. As reported in Table 8, an increase in percentage of FA leads to a significant decrease in the average ultimate tensile strain and also results in a relatively modest decline in the static elasticity modulus. This denotes that using FA to replace OPC may slightly reduce the crack resistance capacity of concrete.

Table 8 Mechanical properties of concrete

Mix	Ultimate Tensile Strain ($\times 10^{-6}$)				Static Elasticity Modulus ($\times 10^4$MPa)			
	7d	28d	90d	180d	7d	28d	90d	180d
C-1	65.0	79.5	86.8	-	3.03	3.98	4.38	-
C-2	45.8	63.0	68.7	71.2	2.73	3.50	4.28	4.69
C-3	36.7	47.5	73.2	74.9	2.65	3.46	4.21	4.63

Figure 8 illustrates the test results of drying shrinkage of CFA concrete, and the test procedure was also in accordance with DL/T5150-2001. In Figure 8, it presents that the drying shrinkage rises dramatically at the early ages and gradually becomes stable after the age of 180 days. As the replacement percentage rises from 30% to 60%, the final drying shrinkage of concrete drops significantly. The measured drying shrinkage of concrete is much smaller than corresponding mortar, which is thought due to the restraining effect of aggregates.

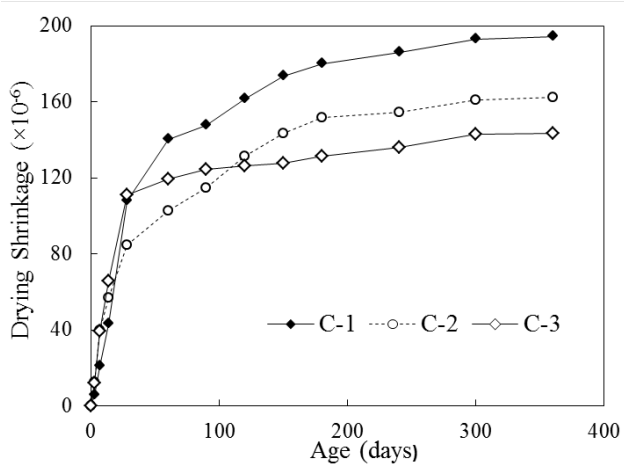

Figure 8 Drying shrinkage of concrete

CONCLUSIONS

According to above analysis, the following conclusions can be summarized:

[1] Fly ash as a replacement material for Portland cement has the effect of delaying the initial and final setting times of cement-fly ash binder. It also has the effect of reducing the compressive and flexural strengths. The reduction is particularly much greater when the percentage of fly ash is higher than 30%.

[2] As for hydration properties, fly ash can effectively reduce the hydration heat evolution of cement-fly ash binder. The reduction coefficient of fly ash on the hydration heat evolution varies between 0.12 and 0.27. Combining the Eq. 1 and the reduction coefficient k, adiabatic temperature rise of cement-fly ash materials can be estimated in engineering applications.

[3] Using fly ash to replace Portland cement in concrete production will significantly affect the adiabatic temperature rise of concrete while other thermal properties (thermal diffusivity, thermal conductivity and average specific heat) are only slightly influenced.

[4] In cement-fly ash concrete, with the replacement percentage of fly ash for Portland cement rising from 30% to 60%, the relationship between compressive strength and flexural strength shows as a similar linear variation. Overall, ultimate tensile strain, static elasticity modulus and drying shrinkage all experience various degrees' reduction.

ABSTRACT

Proper control of early-age cracking risk in concrete as well as optimisation of relevant processes in precast industry requires an adequate knowledge of tensile and fracture properties of concrete at relevant ages. Despite significant past research, such knowledge is currently lacking. This paper presents the recent results of an ongoing research program aimed to address that important knowledge gap. After briefly outlining notable features of an improved direct tensile testing system, the paper presents key results of an experimental investigation into the tensile properties of concrete of age between 2.5 and 9 hours after mixing, both with and without fibres. Compared to concrete without micro-fibre, micro-fibre concrete is found to have more bleeding, considerably lower and more scattered tensile strength and Young's modulus, and higher fracture energy and characteristic length. Possible explanations for such differences are also given. Importantly, the roles of micro-fibres in mitigating the risk of plastic shrinkage cracking are shown to be complex, prompting the need for further study: Although a decreased tensile strength heightens such risk, an increased bleeding helps reduce the risk while the higher fracture energy and characteristic length implies higher ductility.

INTRODUCTION

Knowledge of tensile properties of concrete from very early ages is essential for effective control of both early-age cracking and young concrete in precast industry:

- Early-age cracking may occur in concrete structures from as early as several hours after casting. The underlying mechanism for such cracking is the tensile stress due to restrained deformation reaching the concrete's tensile capacity at that age. Once occurred, existing cracks would develop further if sufficient energy is provided. Indeed, very often, cracks developed at early-ages would propagate and become unserviceable at later stages due to subsequent shrinkage/loading.

  These cracks and their further development at later ages can seriously compromise the integrity, durability, aesthetics, and long-term service life of wide-ranging types of concrete structures. Highway pavements, bridge decks, industrial and residential floors, wharves, podiums, and parking structures, to name a few, are all susceptible to this type of cracking. The current trend of increasing use of concrete mixes with lower water-binder ratios, lower bleed capacities, and higher contents of cement and fine materials, increases the susceptibility of concrete structures to early-age cracking (Wiss, 2011). As a result, despite significant past research (R Springenschmid, 1994; R. Springenschmid, 1998; Wiss, 2011), early-age cracking remains widespread and indeed among the major causes of concrete structures' deterioration (Byard et al., 2010).

- In precast industry, it is highly desirable to release pre-tensioned forces, demoulding and freeing up the casting area as soon as possible, while restricting prestress loss as well as ensuring adequate concrete properties upon releasing (Hernandez, 1975; Levitt, 1990). The lifting anchorage systems are also designed based on concrete properties at a designated early age.

Proper control of early-age cracking risk in concrete as well as optimisation of relevant processes in precast industry therefore requires an adequate knowledge of tensile and fracture properties of the materials being considered. As a result, reliable data on complete tensile stress-strain curves of concrete at relevant ages are needed. Unfortunately, despite significant past research effort, such useful data are currently very limited, especially for concrete during the first hours after mixing. This is possibly mainly due to the considerable challenges in testing early-age concrete, which is both weak and wet. A number of direct tensile testing systems

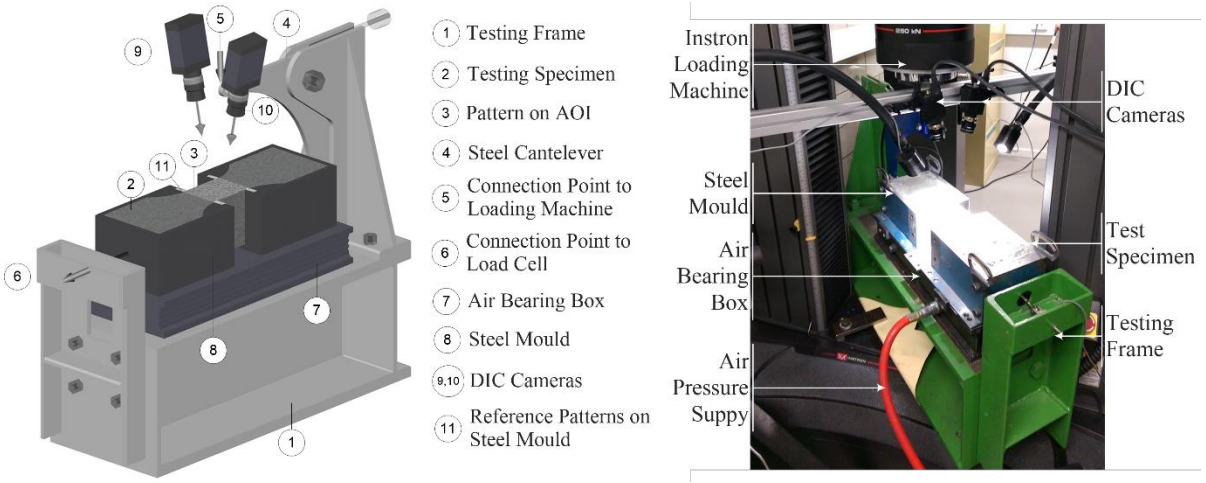
have been developed, each with its own merits and drawbacks as detailed in (Nguyen & Dao, 2014, 2015). An improved testing system that can effectively address major drawbacks in available setups is therefore needed to enable the collection of more reliable data on early-age properties of concrete in direct tension.

In addition, it has also been suggested that aspects of early-age concrete performance can be improved through addition of fibres in concrete mixtures. Although being extensively studied and applied in practice since the late 1960s (Aly et al., 2008; Banthia & Gupta, 2006; Isabel & Ronald; Naaman et al., 2005; Qi et al., 2003; Rahmani et al., 2012; Ziad & Marc, 2002), such effects of fibres on performance of early-age concrete need further investigation to resolve remaining contradictions and unknowns. One of such remaining unknowns is the influence of different types of fibres on early-age tensile properties of concrete: There seems no reported literature on such influence despite its significance.

In this paper, an improved testing system that effectively overcomes major drawbacks in available test setups is first briefly described. Key aspects of the experimental study, relevant obtained test results and their discussion are then presented, followed by summary and conclusions.

DESCRIPTION OF THE DIRECT TENSILE TESTING SYSTEM AND TEST SERIES

The Direct Tensile Testing System



(a) Schematic illustration (b) Photo of test setup

Figure 1 Direct tensile testing system.

Through critical evaluation of merits and drawbacks of available test systems, a new direct tensile testing system with significant improvements has been successfully developed at the University of Queensland. A schematic illustration of the new system, together with a photo of the actual setup, are shown in Figure 1. The test specimen is supported by an air-bearing box ⑦ and has one end fixed to the test frame ① through a load cell ⑥ and the other end being movable and connected to the loading machine⑤. Notable features of this unique test apparatus include:

- The steel mould⑧ is assembled using a magnetic table to ensure a planar bottom surface. The reduced middle region of test specimen has 100x70 mm^2 in cross-section and 70 mm in length (Figure 2).

- Air-bearing box⑦: The upper plate of the air-bearing box has 32 holes symmetrically distributed under the two halves of the mould. The levelness of the upper surface of the air-bearing box after placement in the test position is ensured by using an electronic leveller with an accuracy of 0.1^{o}. During testing, the air bearing box provides a uniform air pressure to float the test specimen, thereby effectively eliminating friction between the specimen and the supporting surface.

- Digital Image Correlation (DIC): The novel application of DIC enables the desired deformation over the whole Area of Interest (AOI, as shown in Figure 2) to be reliably captured in a non-contact way. The successful use of DIC in testing of concrete several hours after mixing has thus effectively addressed major shortcomings of previous set-ups. In this study, two high resolution professional DIC cameras (2448x2048 pixel) are employed to capture the 3D displacement/deformation of the top surface of concrete specimen. Both cameras (⑨,⑩ in Figure 1) are synchronized with the loading

process by a "sync" software developed in-house at The University of Queensland. Four reference pattern areas ⑪ (Figure 1) are also applied to the steel mould at four corners of the AOI to facilitate verification of displacement analysis from DIC system.

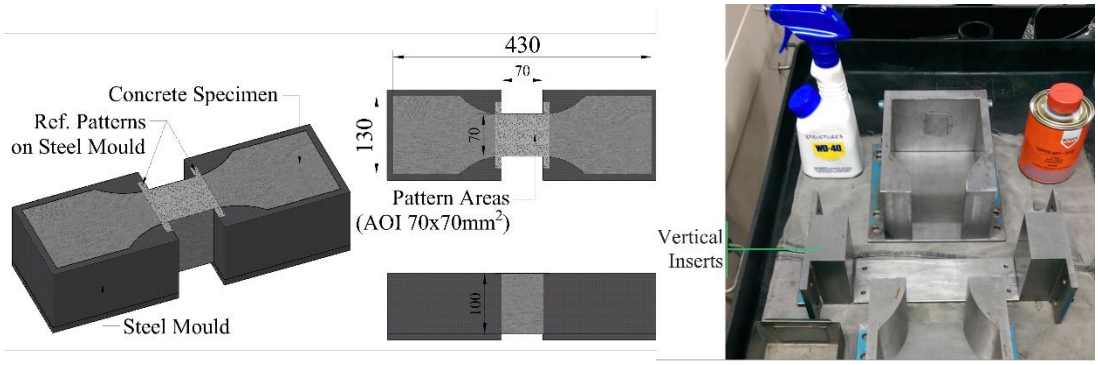


Figure 2 Testing mould and the Area of Interest.

Further details of the testing system, including the critical improvements compared to previous systems as well as the verifications to establish its effectiveness and reliability for early-age concrete testing, can be found elsewhere (Nguyen & Dao, 2014, 2015).

Concrete Mixes and Test Series

Table 1 Concrete mix design (30MPa – 80mm*)

Ingredients	Cement *(kg)*	20mm Hornfels *(kg)*	10mm Hornfels *(kg)*	Coarse Sand *(kg)*	Fine Sand *(kg)*	Water Reducer *(L)*	Water *(L)*	Micro Fibre** *(kg)*
Quantity/m^3	310	790	280	495	366	1.09	195	0.90

Notes: * *30MPa – characteristic compressive strength at 28 days and 80mm – slump;*
** *Micro fibre content is for micro fibre mix only; for normal mix, this amount is zero.*

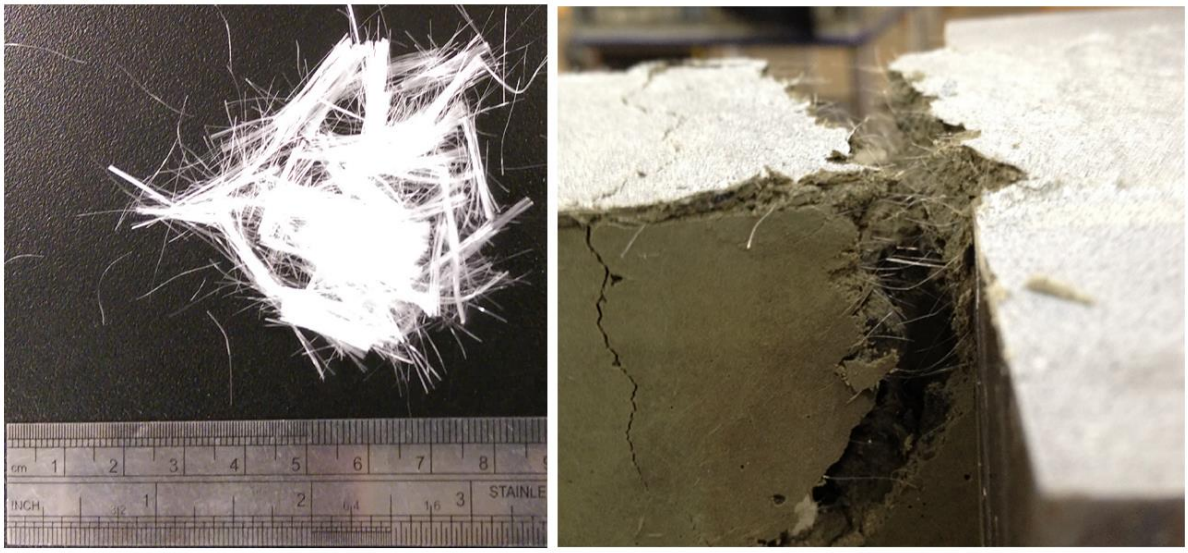
The selection of concrete type depends on its popularity in practice, as well as the susceptibility of the structural members (made of that concrete) to early-age cracking/damage. By that criteria, the concrete mixes 30MPa-80mm, with and without micro fibre were chosen (Table 1). For comparison, fibre content is the only difference between two mix designs. The chosen fibre is 12mm long micro filament made of 100% virgin blended-, non-fibrillating copolymer (Figure 3). Fibre's specific gravity is 0.91 and its tensile strength ranges between 685 MPa and 758 MPa. The product follows ASTM C-1116, Type III, Section 4.1.3 "Synthetic Fiber-Reinforced Concrete and Shotcrete" (FIBERCON, 2015).

In order to have a comprehensive consideration over concrete properties, all ingredients were ensured to be consistent throughout the testing series and were maintained in the same laboratory conditions within the testing period. Regular moisture tests were conducted every three weeks for fine sand, coarse sand and 10mm Hornfels aggregate; from which the actual water amount could be adjusted accordingly. Oven was applied for the first moisture tests, while Speedy Moisture Meter was employed periodically afterward.

The mixing, placement and curing of concrete of both mixes were kept the same as far as practical to ensure similar mix quality. Assuming zero water absorption of the fibre as given in the product data sheets (FIBERCON, 2015), the effect of fibre on effective water content as well as water/cement ratio can be considered negligible.

Testing Procedures

Concrete was mixed by a medium rotating mixer of 70 litre capacity and placed directly into the steel mould, which was then compacted via a vibrating table. Test specimens were subsequently covered by three layers of dump clothe and transferred to the test room. The whole test series was conducted in an air-conditioned room with negligible wind, temperature (18-22^{0}C) and humidity (55%-60%). Concrete age is measured from the time water is added to the mix.



(a) Micro fibres (b) Fibre distribution across a crack

Figure 3 Micro fibres and their typical distribution across a crack surface.

The tensile testing frame was mounted onto the Instron loading machine (of 250 kN capacity) and kept in place by two steel clamps installed at two sides. One 2 kN load cell with high accuracy, the main load recording device, was installed at the fixed end of the testing frame. For each specimen, curing clothe layers were removed about 15 minutes before testing, leaving the top surface for pattern application, which is a vitally important step to ensure the quality of DIC analysis. Flat RustOleum industrial fast drying spray paint was chosen for pattern material due to its fast drying capacity as well as lowest gloss.

In order to put the mould into place, first of all an air pressure level of ~20psi (140kPa), which was sufficient to float the test specimen, was supplied. The test specimen was then carefully placed on the air table and its two ends were connected to the testing frame using rod end linkages and clevises. When the air was still on, an initial tensile load of approximately 0.1-0.2N was applied to ensure straight alignment and minimised initial "lag" at connections.

DIC camera system was then installed with the camera axes focusing on the centre of concrete's top surface. Two cameras were employed into one 3D system. The angle formed by each camera axis and the vertical line perpendicular to the top surface was approximately 10^o-20^o, which is the optimal range for best analysis quality (www.correlatedsolutions.com, 2007). The distance from the camera lens to concrete surface was 20-25 cm. Each camera has a pixel resolution of 2448x2048, and intensity resolution of 8 bit. Camera capturing frequency was 2-5 seconds and the chosen displacement rate was 0.05mm/min.

RESULTS AND DISCUSSION

Throughout the whole test series, tensile stress data was determined from the readings of the 2 kN load cell, assuming uniform stress distribution on any given cross-section within AOI. Tensile strain was obtained from 3D analysis of VIC-3D program. The engineering strain ($\varepsilon_{xx} = \Delta x/L$) was calculated manually from extracted displacement values over a fixed gauge length.

Figure 4 shows typical stress-strain curves obtained for different ages from mixing. The values of ultimate strain ε_o at full separation were also determined for the last tests of each series. From these obtained stress-strain curves, a number of important concrete properties at very early ages can be derived, including tensile strength, Young's modulus, tensile strain capacity and fracture properties as discussed in the subsequent sections.

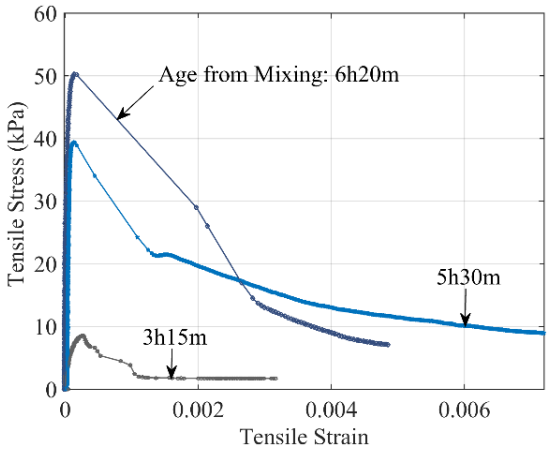


Figure 4 Typical obtained stress-strain relationships at different ages.

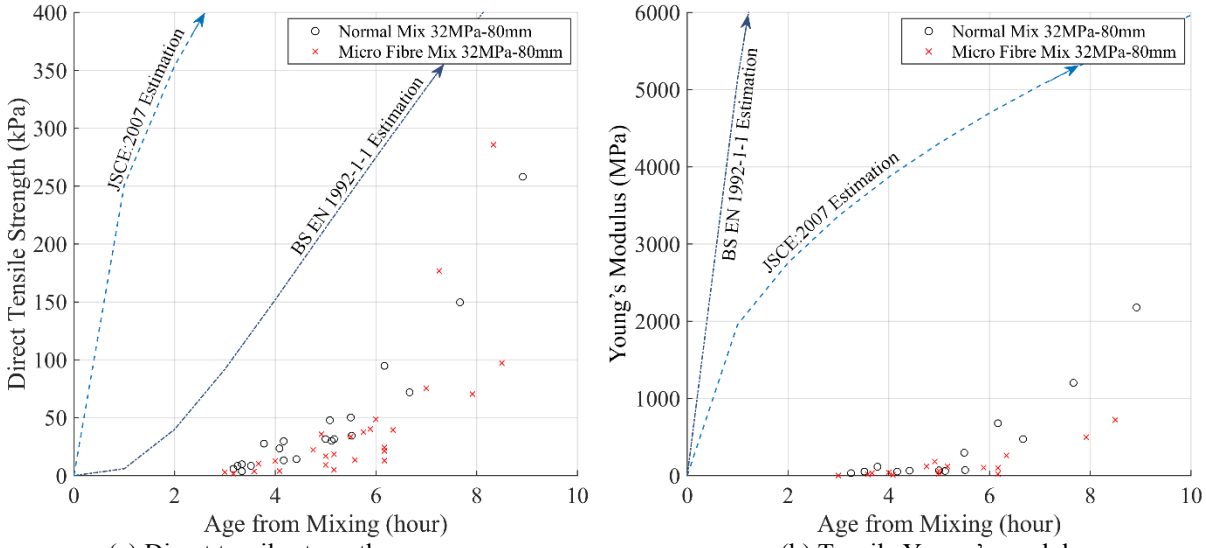
Tensile Strength f_t and Young's Modulus E_t development

The time evolution of tensile strength and Young's modulus is plotted in Figure 5. It can be observed that concrete tensile strength is negligibly small during the first 3 hours but accelerates quickly to several times larger in the next few hours (Figure 5a). A development trend is also observed, being in good agreement with previous studies although at different developing rates (V. T. N. Dao et al., 2009; Kasai et al., 1974). Such development is consistent with the hydration process: (i) The dormant period with minimal hydration lasts for approximately 2-4 hours for normal concrete as used in this study; (ii) Following initial set, significant ongoing hydration results in rapid increase in tensile strength (Department of Transportation (USA), 2007; Neville, 1986).



(a) Direct tensile strength. (b) Tensile Young's modulus.

Figure 5 Development of tensile strength and Young's modulus.

Comparing the measured tensile strengths of less than 50 kPa during the first 6 hours after mixing as in Figure 5a with the possible maximum tensile stress in young concrete due to matric suction of higher than 60 kPa (V. N. T. Dao et al., 2008), the necessity of protecting early-age concrete is clear.

Further investigations regarding tensile strength of two test mixes gives the following characteristics:

- Recorded tensile strength of concrete without micro-fibre are more consistent therefore an obvious developing trend is formed. However, greater deviation in recorded results is observed for the case of micro-fibre mix, which commences from approximately 4 hours of age and further increases at later ages. Fibre distribution (including global- and local- fibre density), fibre alignment as well as the number of fibres present across a specific crack surface are thought to be contributory factors (RILEM

TC 162-TDF, 2001). Typical distribution of micro fibres across a concrete crack surface is shown in Figure 3.

- Visual inspection clearly indicates higher bleed water accumulated on the top surface of test specimens of micro-fibre mix, compared to those of mix without micro-fibre. This phenomenon is consistent with observations in other studies (Aly et al., 2008; Qi et al., 2003; Toutanji et al., 1998). Such increased bleeding is thought a result of fibres acting as tiny "fluid channels" along the length of fibres, facilitating vertical water movement.

- Interestingly, the direct tensile strength of micro-fibre mix in most cases is lower than that of normal mix without micro-fibre (Figure 5a). This is possibly due to the presence of micro-fibre in mix design: Since the fibres are chemically inert (FIBERCON, 2015), their bond with surrounding concrete mostly derives from the physical interaction and friction with the hydrated cement paste. Such bond might be smaller than the inherent bond within hydrated cement paste, thus compromising the tensile property of concrete specimens with micro-fibres. Moreover, concretes with fibre addition have been shown to have higher meso-pore sized porosity compared to that of the reference normal concrete (Aly et al., 2008).

  The roles played micro-fibres in mitigating the risk of plastic shrinkage cracking are thus complex: (i) The possible decreased tensile strength heightens such risk; (ii) An increased bleeding discussed above helps reducing the risk; and (iii) The higher fracture energy and characteristic length, as discussed later, implies higher ductility.

  It should also be noted that fibres and their positive effects on early defects such as plastic shrinkage cracking (from the first hour after mixing (Qi et al., 2003)) and drying shrinkage cracking (for hardened concrete) have been for decades investigated and acknowledged (Banthia & Gupta, 2006; Isabel & Ronald; Qi et al., 2003; Rahmani et al., 2012; Shah & Daniel, 1994; Ziad & Marc, 2002). Such studies have a similar approach which relies mainly on the strain-related criteria such as crack lengths, maximum crack widths as well as total crack areas. By such approach, the main focus is mostly placed on the ability of fibres in crack opening control, rather than cracking prevention. From Figure 5a, it clearly indicates a necessity to re-assess the role of fibre addition for young concrete in a more comprehensive way, incorporating pre-crack properties into consideration as well.

Young's modulus has similar developing trend to that of tensile strength, although considerable increase is only observed from around 5 hours after mixing, as evidenced in Figure 5b. In this study, Young's modulus is found by:

- Linear curve-fitting to the ascending part of stress-strain curves between ~5% and 40% of the tensile strength, following available standard (Standards Australia, 1997); in a combination with

- Visual inspection of the linear characteristic of the stress-strain curve within chosen range.

Once again, the obtained Young's modulus for micro fibre mix is considerably lower than that for normal mix at most of testing ages (2.5-9 hours), both in value and rate/speed (Figure 5b).

Also in Figure 5, tensile strength and Young's modulus development trend are also placed into a qualitative comparison with the estimation methods in currently available design standards. Eurocode's BS EN 1992-1-1:2004 (British Standard, 2004) and Japanese's JSCE: 2007 (JSCE Concrete Committee, 2007) are among very few (if not the only two) providing formulae to estimate early-age tensile properties. The estimation curves shown are determined for Ordinary Portland Cement and at the same designed characteristic compressive strength, with concrete ages input in day(s). In Figure 5a, BS EN 1992-1-1 seems to give a good agreement with this study over tensile strength's development. For the case of Young's modulus, both standards show differences both in value and in trend with this study and also differ significantly from each other.

Strain at Peak Stress ε_c

The time evolution of the obtained strain at peak stress is plotted in Figure 6, from which several characteristics can be identified, including:

- Strain at peak stress is observed to decrease over time for both mixes within the test age range (2.5-9 hours), and possibly reaching a minimum value at approximately 8-9 hours (Figure 6a). This corresponds well with minimum values at around 10 hours reported in (Kasai et al., 1972).

- Although with more variation, micro fibre mix experiences little difference between its strain at maximum stress and that of the reference normal mix in the first 5 hours after mixing (Figure 6a). However, for later ages (5-9 hours), a relatively higher level of strain at peak stress is observed, corresponding to that reported in (Ziad & Marc, 2002). Fibre-concrete bond development is thought to be the reason for such difference.

- A comparison with previous studies in Figure 6b indicates good agreement with this study in terms of basic trend and value. The lowest points appear at around 5-10 hours after mixing with the values ranging from ~20με (Roziere et al., 2015) to ~150με (Hannant et al., 1999; Kasai et al., 1972). It should be noted that concrete plastic shrinkage within 3-9 hours of age, depending on the amount of superplasticizer, is between ~50με and 1200με (Holt & Leivo, 2004). With early-age concrete experiencing shrinkage that can be significantly higher than its strain capacity, the risk of early cracking and thus the critical need of an appropriate curing method are again clearly highlighted.

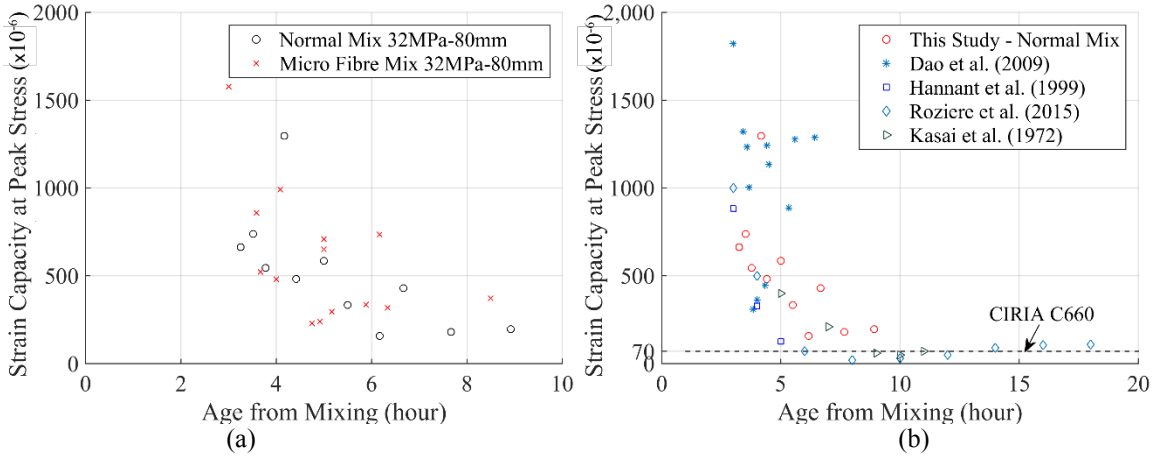


Figure 6 (a) Strain et peak stress evolution over time and (b) Comparison with previous studies, including (Bamforth, 2007; V. T. N. Dao et al., 2009; Hannant et al., 1999; Kasai et al., 1974; Roziere et al., 2015).

- Besides Eurocode's BS EN 1992-1-1:2004 (British Standard, 2004) and Japanese's JSCE: 2007 (JSCE Concrete Committee, 2007), CIRIA C660 (Bamforth, 2007) is among very few design specifications provided for early cracking control. The specification suggests tensile strain capacity as the design criteria, which is 70με for all types of concrete (Figure 6b). Compared to this study as well as previous ones, such suggestion seems to be adequate for concrete without fibres but somewhat conservative for micro-fibre concrete.

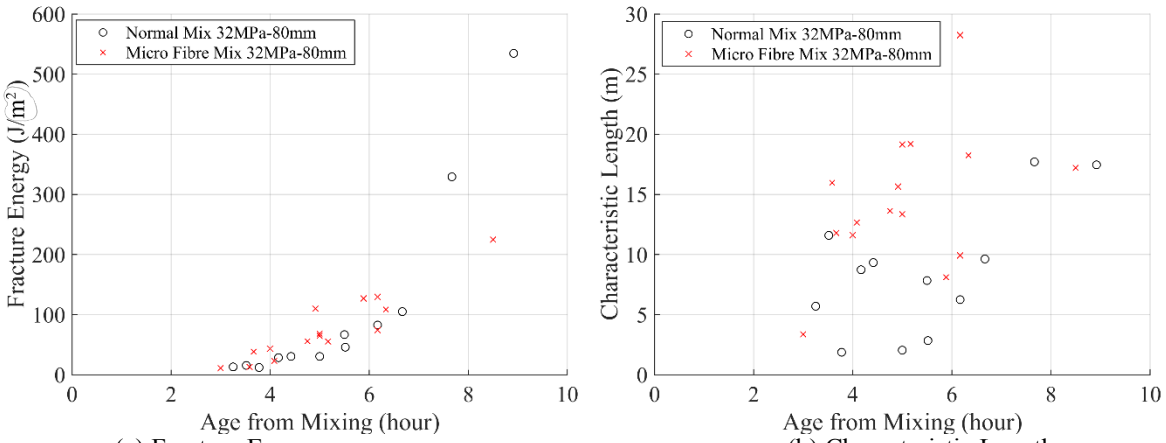
Fracture Properties

Using the obtained test data, fracture properties can be calculated based on a stress-crack opening curve, following the fictitious crack model proposed by Hillerborg (Hillerborg, 1985). The development over time of fracture energy G_F, defined as the area under the stress-crack opening curve (excluding the elastic shortening when cracking occurs), is plotted in Figure 7a. From the figure:

- G_F is observed to increase over time, with more consistent trend for normal concrete without micro-fibre, compared to that of micro-fibre concrete. Fibre distribution and alignment as well as number of fibres crossing the fracture area are thought to be the main factors to cause greater variation of G_F in fibre mix (Löfgren et al., 2008). It should be noted that due to the very definition, fracture energy is very sensitive to the reliability of displacement measurement setup. A comparison with previous study (V. T. N. Dao et al., 2009) for the same mix design and similar testing system shows large difference in G_F's development trend because of different displacement recording systems employed (Nguyen & Dao, 2015). This highlights the necessity of reliable measurement of displacement - The novel adoption of DIC system in this study for reliable non-contact displacement tracking method is therefore an important improvement.

- Within the testing period (2.5-9 hours), G_F of micro fibre mix is found to be slightly higher than that of the reference normal mix at a specific test age. As discussed previously, the addition of micro fibres

produces two counteracting effects on early-age concrete behaviour, which in turn deviate G_F. Lower tensile strength reduces G_F but at the same time, higher post-crack deformation increases it. Although the obtained results are generally in good agreement with other studies (Banthia & Gupta, 2006; Isabel & Ronald; Rahmani et al., 2012; Ziad & Marc, 2002), "high effectiveness" or "significant crack delay and reduction" of fibres are not observed in this study.



(a) Fracture Energy (b) Characteristic Length

Figure 7 Development of fracture energy and characteristic length.

Figure 7b shows the characteristic length l_{ch} development:

- Although with large scatter due to the accumulation of different uncertainties in E_t, f_t and G_F, an increase trend from very low value (approximately 1-2m) is also observed for both mixes within 2.5-7 hours of age, which corresponds to Dao et al. (V. T. N. Dao et al., 2009) and Østergaard (Østergaard, 2003). From 7 hours after mixing, the trend seems to stabilize and slowly decrease at around 17m. If combined with the observation in previous study (Østergaard, 2003) for the ages after 10 hours, l_{ch} after reaching the indicated peak will decline, according to the growth of concrete brittleness.

- As the definition implies, l_{ch} is proportional to fracture energy G_F and to the inverse of tensile strength f_t. Therefore, with lower tensile strength f_t and higher value of G_F, the characteristic length of micro fibre mix clearly demonstrates higher values than that of the reference normal one, for most of test ages. Higher characteristic length of micro fibre mix indicates higher ductility, which is consistent with general understanding of basic roles of fibre addition (Karihaloo, 2015).

SUMMARY AND CONCLUSIONS

With the aim to address the knowledge gap of concrete tensile properties at very early ages, this study was conducted by employing an improved direct tensile testing system with the application of DIC displacement measurement method. Two mixes with and without synthetic micro fibre addition were investigated for their tensile properties of between 2.5 hours and 9 hours after mixing. The paper has presented key aspects of the employed testing system as well as discussion of obtained results. Major conclusions drawn in this paper include:

- Compared to concrete without micro-fibre, micro-fibre concrete has
  - more bleeding;
  - considerably lower and more scattered tensile strength and Young's modulus;
  - similar values of strain at peak stress;
  - slightly higher fracture energy;
  - higher characteristic length.
- Possible explanations for such differences between concrete with and without micro-fibre are also given. The increased bleeding is likely a result of fibres acting as tiny "fluid channels" facilitating bleeding process. The possible lower bond between fibres and surrounding matrix compromises the tensile properties of concrete specimens with micro-fibres. Fibre distribution and alignment as well as the number and nature of fibres crossing crack surfaces contributes to the scatter of properties of micro-fibre concrete.

- The roles played by micro-fibres in mitigating the risk of plastic shrinkage cracking are thus complex, prompting the need for further study: Although a decreased tensile strength heightens such risk, an increased bleeding helps reduce the risk while the higher fracture energy and characteristic length implies higher ductility.

ABSTRACT

The development of cement-based composites has been fruitful in the recent years. It is important to examine the new materials and technologies so they can fulfill repairing and strengthening applications in the structural engineering fields. An experimental study on the behavior of reinforced concrete beams strengthened in shear using an externally applied fiber reinforced cementitious matrix (FRCM) is presented. The PBO-FRCM system consists of two components: the reinforcing mesh is Polyparaphenylene benzobisoxazole – PBO fiber composite and the bonding agent is cementitious matrix. The test variables included two different configurations of U-wrapped systems and the PBO reinforcement's ratio. The aims of this study were to investigate the effectiveness and the shear performance of the PBO-FRCM system for strengthening reinforced concrete beams in shear. All the beams were instrumented and tested under four-points loading. The test results included the observed shear contribution of the PBO-FRCM system and the failure mode of the strengthened beams.

INTRODUCTION

Numerous reinforced concrete bridges and structures around the world are currently in need of repair or complete replacement as they approach the end of their service lives. Increases in traffic volume, traffic loads, and corrosion-induced deterioration are necessitating significant expenditures to strengthen and rehabilitate existing structures (Baggio et al., 2014). Of the 163,000 single span concrete bridges in the United States, 23% are considered structurally deficient or functionally obsolete (Baggio et.al, 2014). In the last few decades, the fiber reinforced polymer systems have been widely used for retrofitting and strengthening reinforced concrete structural members. Although the use of fiber reinforced polymers has proven to give excellent performances both in terms of bonding and load carrying capacity, some drawbacks exist. The epoxy resin, in fact, has a low permeability, diffusion tightness, poor thermal compatibility with the base concrete, poor fire resistance, susceptibility to UV radiation and low reversibility (Ombres, 2011; Sveinsdóttir, 2012). As a result of these problems, alternative strengthening systems with cement based bonding agents were invented. One of these systems was PBO-FRCM system. The mechanical and durability properties of this system have been verified by Arboleda (2014) . It was concluded that this system could address the problems regarding fire resistance, moisture resistance, and energy absorption. Its bond performance and flexure carrying capacity have been examined by many authors (Ombres 2011; Babaeidarabad et al., 2013; Loreto et al. 2013; D'Antino et al., 2014). The results of the experimental studies have shown the PBO-FRCM system's great influence in enhancing the flexure carrying capacity of RC beams and improving in bond performance among the conventional FRP system. In spite the fact that the shear failure of a concrete structure is a catastrophic failure where no warning is observed prior its occurrence (Li et al., 2001), finite experimental data are available on using the PBO-FRCM system to strengthen RC beams in shear. Baggio et al. (2014) used U-wrapped fiber reinforced cement matrix strips to strengthen reinforced concrete beams in shear and the results have shown that the PBO-FRCM system can effectively enhance the shear carrying capacity by 30%. Diagonal shear failures followed by debonding of the FRCM system were observed. This work was conducted to study the shear performance of RC beams strengthened with an externally bonded PBO- FRCM system in U-wrapped continuous and strip configurations. The crack propagations and beam failure behavior were inspected. The

percentage of increase in load carrying capacity and ductility performance of the PBO- FRCM system are discussed as well.

EXPERIMENTAL PROGRAM

Test Specimens and Materials

The beam dimensions used in this study were 2133 mm (84 in.) long, 305 mm (12 in.) deep, and 203 mm (8 in.) wide. The distance between the supports was 1905 mm (75 in.). The center to center distance between the positions of load was 686 mm (27 in.). Five RC beams were fabricated. Each beam specimen had longitudinal and transverse reinforcements. The flexural reinforcements consisted of three 22 mm (No. 7) diameter as bottom reinforcements and two 10 mm (No. 3) diameter as top reinforcements. The shear reinforcements consisted of 10 mm (No. 3) diameter stirrups placed at 127 mm (5 in) spacing. Figure 1 is shown the dimensions and reinforcements' detail. The longitudinal steel reinforcements had a yield stress of 412 MPa (60 ksi) .The shear reinforcements had a yield stress of 345 MPa (50 ksi). The yield strength of each rebar type was determined based on ASTM A370 (2012a) of three coupon tested samples.

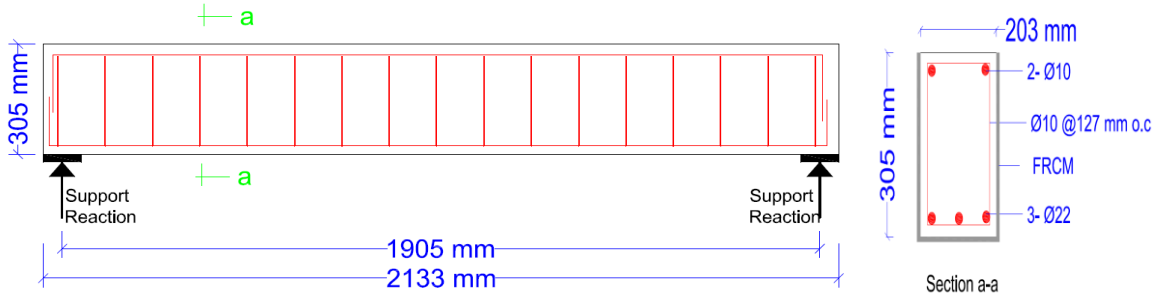

Figure 1 Typical geometry and reinforcements of the beam specimens

The concrete material properties were obtained from a series of standard cylindrical specimens with 100 mm (4 in.) diameters and 200 mm (8 in.) heights, ASTM C39/C39M (2014) and C469/C469M (2014) were followed. The measured compressive strength and elastic modulus were 45MPa (6500 psi) and 33(4800 ksi) respectively at the date of testing beam specimens. Specifications of the PBO-fiber and the cementitious mortar manufactured by Ruredil Company for construction chemicals and building technology, Italy are presented in Table 1.

Table 1 PBO-FRCM properties by Ruredil company

PBO Fibers Properties	
Density	1.56 g/cm^3 (0.056 lb/in^3)
Tensile strength	5.8 GPa (840 ksi)
Modulus of elasticity	270 GPa (39 160 ksi)
Ultimate deformation	2.15%
Inorganic Matrix Properties	
Compressive strength	40.0 MPa (5800 psi) at 28 days
Secant modulus of elasticity	> 7.000 MPa (1015 psi) at 28 days

The compressive strength of the cementitious mortar was found by testing five 50 mm (2 in.) cubes in accordance with ASTM C109 (having an average of 31 MPa (4500 psi) at the time of the beam specimen testing.

PBO-FRCM Strengthening Schemes

One unstrengthened beam served as a control specimen. Vertical U-wrapped PBO sheet was used as it is the most effective strengthening configuration for reinforced concrete beams. Two different configuration of strengthening were considered in this study. Two beams were strengthened with strips of the PBO-FRCM system that had a 102 mm (4 in.) width with 204 mm (8 in.) center to center spacing as shown in Figure 2a.The two other beam specimens were strengthened with continuous strips of the PBO-FRCM system over a width of 560 mm (22 in.) as shown in Figure 2b. The test matrix is represented in Table 2.

Table 2 Test matrix

Specimen ID	FRCM Type	# of Plies	Ply Width wf, mm (in)	Strip Spacing Sf, mm (in.)
B-01	N/A	N/A	N/A	N/A
B-02	Strips	1	102 (4)	204 (8)
B-03	Strips	4	102 (4)	204 (8)
B-04	Continuous	1	560 (22)	_
B-05	Continuous	4	560 (22)	_

Specimen Preparation

The castings of the beams were made by ready-mix concrete. The specimens were left in room conditions and were strengthened after a concrete aging period of 28 days. To ensure a good bonding, the bottom surface and the sides of each beam specimen were sandblasted and cleaned by vacuum. The edges of the beam were rounded for 19 mm (¾ in.) radius based on the recommendation of ACI549R (2013) to prevent stress concentration failure at the edges. Before the application, the concrete surfaces were wet. The installation procedure of the PBO-FRCM systems was based on the recommendations of the manufacturer and ACI549R (2013). The first step involved applying the non-thixotropic mortar with polypropylene fibers (Exocem FP) to provide perfect adhesive to the concrete surface. In the second step, the first mortar layer (X MORTAR 750) was laid on for about 3 mm (0.12 in.) in thickness. In the third step, The PBO mesh was applied and pressed slightly into the first mortar layer to ensure a good contact with the mortar. Finally, the second mortar layer was covered with the PBO mesh and leveled to have a smooth finishing surface. In the case of applying four plies of PBO mesh, the procedure was repeated until all layers were applied and covered by the cementitious mortar. All strengthened beam specimens were cured for 28 days under the laboratory environmental conditions before any testing. Figure 3 shows the material and application steps for the PBO-FRCM strengthening system on the RC beams.

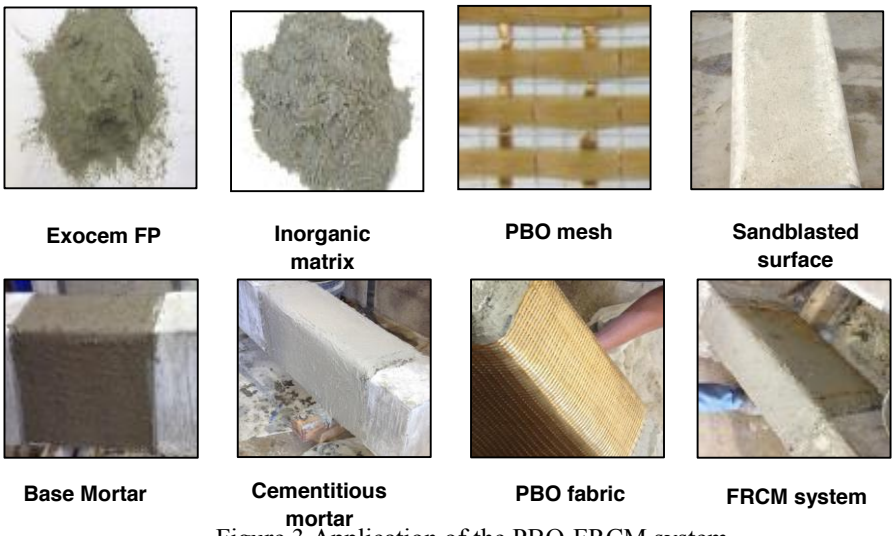

Figure 3 Application of the PBO-FRCM system

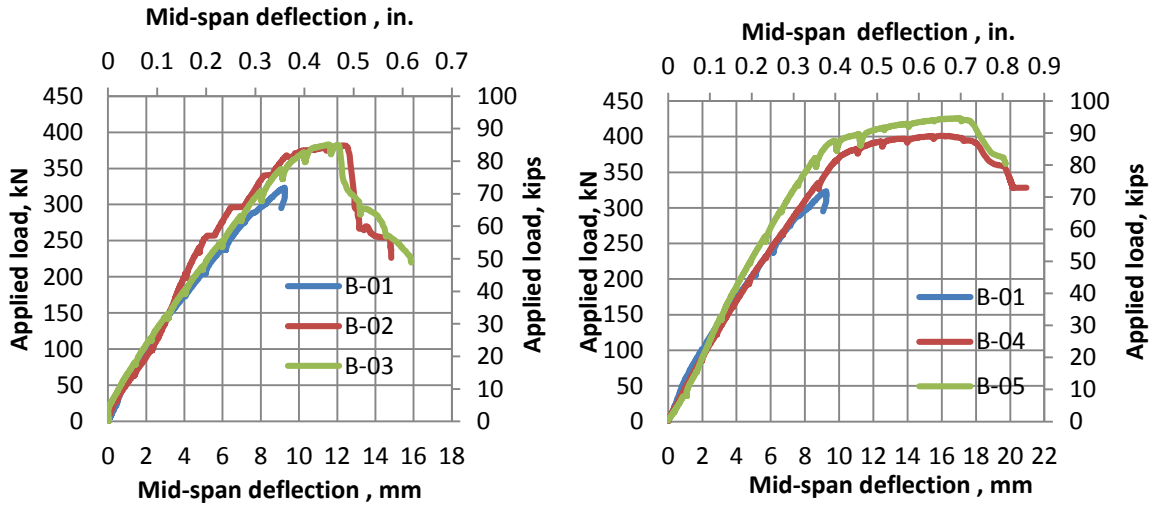
Instrumentation and Testing Procedure

All the beams were loaded in four points loading using a vertically positioned MTS actuator as shown in Figure 4. All beam specimens were tested monotonically at a displacement rate control of 1.3 mm/min (0.05 in/min) up to the failure. Displacements were measured at mid-span using a linear variable differential transducer (LVDT) seated on one side of the beam specimens. A strain gauge (type 250BG) with a 6.35mm (0.25 in.) gauge length was used to record the strains data for longitudinal, transverse reinforcements and the PBO-FRCM. One strain gauge was set at the mid span of the longitudinal rebar .one strain gauge was set at the close d stirrup to the support. Three strain gauges were set on the PBO-FRCM strengthening system at each side of the beam on three different levels. The measurements of the load versus mid-span displacement were collected from the data acquisition system for each tested beam.

Figure 4 Beam test set- up

Test Results

The load–midspan deflection relationship is shown in Figure 5 for all beam specimens. The control beam (B-01) failed in shear, as expected, through the formation of diagonal tension cracks in the shear span as shown in Figure 5a. The ultimate load was 325 kN (73 kips) with a midspan deflection of 9.25 mm (0.36 in.). The beam specimen that strengthened with one ply U- wrapped strips of the PBO-FRCM (B-02) was failed by a diagonal tension shear failure followed by slippage of the PBO-FRCM system as seen in Figure 5b. The ultimate load was 383 kN (86 kips) with a midspan deflection of 12.44 mm (0.49 in.). The beam specimen that were strengthened with four plies U-wrapped strips of the PBO-FRCM (B-03) failed by a diagonal tension shear failure followed by debonding of the PBO-FRCM system as seen in Figure 5b. The beam specimen (B-03) exhibited the same failure load and midspan deflection as beam specimen (B-02). The beam specimens that were strengthened with continuous U-wrapped strips (B-04) and (B-05) failed by shear flexure cracks. The ultimate loads for these beams were 400 kN (90 kip) and 423 kN (95 kip) with a midspan deflection of 16 mm (0.62 in.) and 17 mm (0.67 in.) respectively. There were no sudden brittle shear failures observed for the strengthened beams. That is concluded the effective contribution of the closed spaced stirrups, the dowel action provided by three 22 mm (0.85 in.) in diameter (No.7) longitudinal rebars, and the PBO-FRCM strengthening system. The PBO-FRCM strengthening system enhances also the stiffness of the beam specimens. As the load started to increase the strengthen beam specimens observed higher stiffness as seen in Figure 5. Especially, the continuous U-wrapped strengthening increased significantly the beam specimen's stiffness. In addition, using four plies of the PBO-FRCM system were more effective than one ply. The stepped drop in the load carrying capacity which seen in Figure 5, represents the loss in the stiffness of the beam specimens as the cracks developed and become wider. Table 3 is presented the percentage increase in the load carrying capacity and displacement ductility over the control beam specimen.



(a) (b)

Figure 5 Load- midspan deflection curves

Table 3 Load carrying capacity and ductility

Specimen ID	Experimental Ultimate Load, kN (Kips)	% Increase in Load Carrying Capacity	Ultimate Deflection mm (in)	% Increase in Ductility
B-01	325 (73)		9.24 (0.36)	
B-02	383 (86)	18%	12.44 (0.49)	35%
B-03	384 (86)	18%	11.53 (0.45)	25%
B-04	400 (90)	24%	16 (0.62)	72%
B-05	427 (96)	32%	17 (0.67)	85%

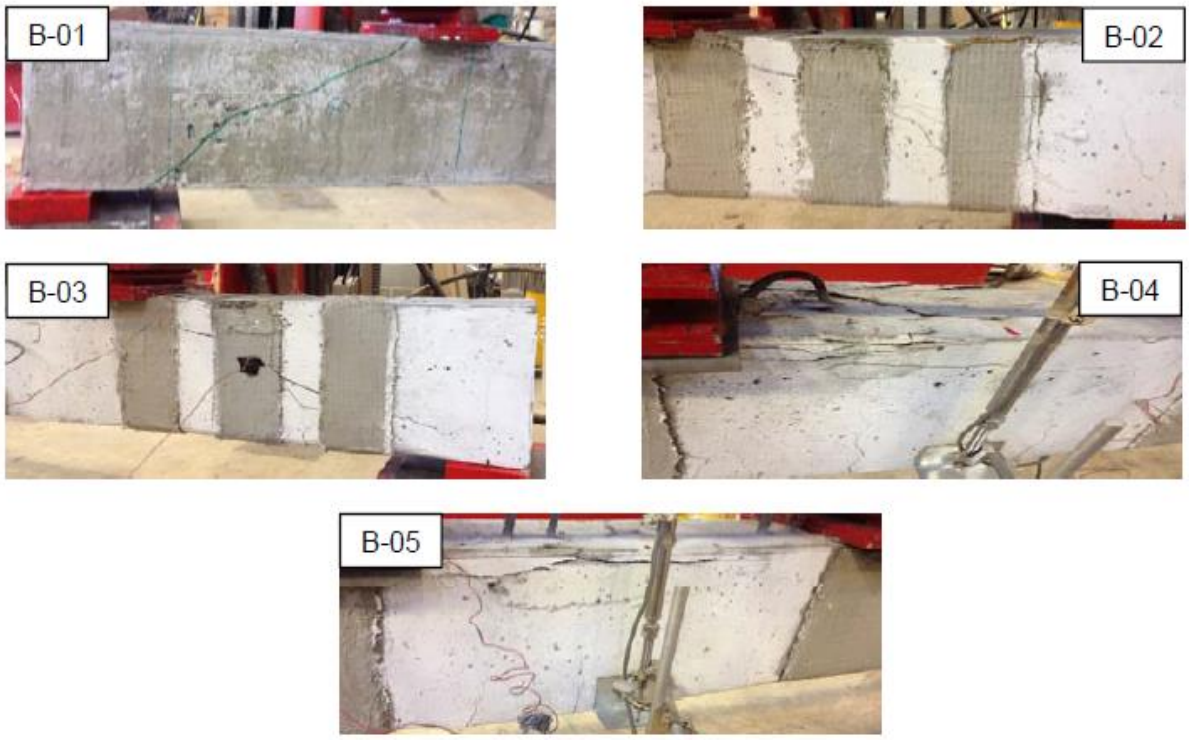


Figure 6 Failed beam speciemns photes

Crack progression in the beams (B-01), (B-02) and (B-03) began with the appearance of shear cracks near the supports and extended diagonally toward the loading points. As the load was increased the cracks became wider until the final drop in the load carrying capacity where observed. Wider cracks were observed in the beam specimen (B-03) than that observed in beam specimen (B-02). That can be explained due to the variation in the shear strength provided by the aggregate interaction which had less attribution in beam specimen (B-03).Then the wider cracks engaged the two plied of the PBO-FRCM system to carry the shear load till rupture so the other outer plies had no longer contribution in the shear carrying capacity and that terminate the test with the same load carrying capacity as beam specimen (B-02). The beam specimens (B-04) and (B-05) observed a different behavior. The beam specimens provide higher stiffness as seen in Figure 5b. No shear cracks were observed during the test. However after removing the PBO-FRCM system, there were finer shear cracks close to the face of the supports. The transverse reinforcements were reached the yield stress and the continuous U-wrapped PBO-FRCM system holds the beam specimens against brittle shear failure. Then the mode of failure was changed to flexure through unwrapped regions followed by crushing in the concrete as seen in Figure 5 and 6. The higher ductility provided where the longitudinal reinforcements become more active to resist loads in charge of continuous U-wrapped PBO-FRCM against shear

failure. The recorded strains in the longitudinal and transverse reinforcements with the PBO-FRCM system are shown in Table 4. The strain reading in the longitudinal rebars and stirrups were yielded in all beam specimens .The strain readings for the PBO-FRCM system represented the higher recorded value out of six readings for each beam. Although, it was hard to say if those values represented the maximum reachable value in the PBO-FRCM system since the shear crack path is unexpected and the location of the strain gauges were not perfectly match the actual crack path.

Table 4 Strain readings in Rebar's and PBO-FRCM

B02	0.0074	0.0022	0.0013
B03	0.0074	0.0060	0.0028
B04	0.0070	0.0025	0.0020
B05	0.0060	0.0024	0.0020

CONCLUSIONS

The PBO-FRCM technology is still a novel system under investigation and more experimental results are in need to understand better the performance of the PBO-FRCM system in shear strengthening applications. The main findings of this work are summarized as follows:

1- No debonding between the base concrete and the cementitious bonding agent was noticed.
2- The strengthened beams had more ductile behavior near failure than the control beam. That concluded the PBO-FRCM system's effectiveness in enhancing the shear carrying capacity of reinforced concrete beams.
3- The continuity of the U-wrapping would minimize the effect of stress concentration presented in strip configurations. That provided a better ductile behavior with an increase in the load carrying capacity of 24% for beam specimen strengthened with one ply and 32% for beam specimen strengthened with four plies.
4- The continuous U-wrapped strengthening configuration has a great impact on enhancing beam specimens' stiffness.
5- No increase in the load carrying capacity observed for using four plies of the PBO-FRCM system in strip configuration verses one ply.
6- Strengthening with continuous U-wrapped PBO-FRCM system had a great impact on enhancing the displacement ductility performance in comparison with one ply.

ABSTRACT

Many studies have been conducted for enhancing the positive moment capacity of the mid-span areas of reinforced concrete (RC) beams strengthened with fiber reinforced polymer (FRP) reinforcement under monotonic increasing loads. However under seismic actions, the support regions of beams may also require retrofitting. In such cases, retrofitting should be effective under reversed cyclic flexural actions. According to the best knowledge of authors, there is no study investigating this important issue in the literature. Therefore, the present study focuses on retrofitting of beam support regions under reversed cyclic flexural moments. As the initial stage of a more comprehensive testing program, three full-scale RC beam-column-slab sub-assemblages were tested. The sub-assemblages also included a part of transverse beams perpendicular to the main beam tested. One specimen was tested as a reference specimen while the remaining two specimens were tested after being retrofitted with near surface mounted (NSM) carbon fiber reinforced polymer (CFRP) ropes with two different details in terms of anchorage of the CFRP ropes into joint region. The anchorage of CFRP ropes was provided by NSM application over the slab next to the column in one of the specimens, while CFRP rope was anchored by epoxy adhesive within the joint core by embedding it through a drilled hole on the column in other specimen. The effectiveness of the proposed anchoring methods was investigated through experimentally. The findings of the study indicated that the specimen retrofitted with NSM anchoring method achieved a remarkable enhancement in flexural capacity, whereas, anchoring through embedment of the CFRP rope within the epoxied drilled hole was not that successful.

Anchorage, embedment through section (ETS), flexure, near surface mounted (NSM), reinforced concrete beam, carbon fiber reinforced polymer (CFRP) rope.

INTRODUCTION

Earthquakes have proven that many reinforced concrete (RC) beams are required to be retrofitted. Major studies about the enhancement of flexural behavior of RC beams greatly benefit from the usage of fiber reinforced polymers (FRPs) (Fanning and Kelly 2001; Brena et. al. 2003; Shin and Lee 2003; Kotynia et al. 2008). The most recent and promising technique for retrofitting of RC beams with FRPs is known as near surface mounting (NSM). Although, it is a recent method, the strength capacity increase of NSM strengthened beams was validated by many studies (De Lorenzis and Nanni 2001; Hassan and Rizkalla 2003; Teng et al. 2006; Lee and Chang 2013; Wu et al. 2014). Reviewed studies mainly focus on retrofitting the mid-span areas of the beams without taking into account the earthquake effects at the support regions. However, in the case of earthquake actions, support regions of beams can be critical and may require retrofitting.

Limited number of studies have been conducted about the seismic behavior of RC members strengthened with FRP materials by using NSM method (Barros et al. 2008; Bournas and Triantafillou 2009; Goksu et al. 2012; Vrettos et al. 2013). According to the best knowledge of the authors, no studies in published literature have been found on the seismic behavior of retrofitting of RC beam support regions with NSM method.

The present study focuses on the enhancement of the flexural performance of support regions of beams using NSM method under reversed cyclic loadings which resemble the earthquake actions. The specimens realistically represent part of an actual building with columns of two consecutive stories, main beam, slab and transverse

beam. Therefore, it can be asserted that the outcomes of the study are not valid only for laboratory conditions, but they are also valid for real three-dimensional structures.

Providing a sufficient anchorage length for main reinforcing bars is vital for retrofitting of the support regions of beams. Therefore, in the scope of the study, two different techniques were used for anchorage of carbon fiber reinforced polymers (CFRP) ropes within the beam-column joint. For the first anchorage type (Ret1), the CFRP rope was anchored inside the square grooves on the surface of the transverse beam next to the column side surface like the case of typical NSM method. For the second anchorage type (Ret2), a recently developed method, named as embedded through-section (ETS) was used. The results of several studies indicated that ETS technique is very effective for shear retrofitting of RC beams (Valerio et al. 2009; Chaallal et al. 2011, Mofidi et al. 2012). Also, Mofidi et al. (2012)'s study indicated that it is also a very promising method for usage of end anchorage. In the proposed study for the second specimen, the CFRP rope is anchored by embedding inside a pre-drilled epoxied circular hole throughout the bottom section of upper story column.

A new kind of CFRP reinforcement defined as CFRP rope was used for retrofitting. Since it is a new material, very few studies were conducted with CFRP ropes for concrete confinement and enhancement of shear capacity of beams (Rousakis 2013; El-Saikaly et al. 2014). In the published literature, no study was found on enhancement of flexural capacity of beams with CFRP ropes except the work done by (Kaya 2014, Kaya et al.).

The findings of the study indicated that specimens retrofitted with FRP ropes using NSM anchoring method achieved a remarkable enhancement in flexural capacity, whereas, anchoring of the CFRP rope through embedment within the epoxied drilled hole was not that successful.

EXPERIMENTAL PROGRAM

Design and Construction of Specimens

The features and designations of specimens used in this paper are shown in Table 1. In this table, f'_c is the characteristic compressive strength of concrete. The compressive strengths in Table 1 were calculated according to the average compressive strength are the average of compressive strengths of 83×83 mm core samples tested in accordance with ASTM C39/C39M-05 (ASTM 2005) standard. The day of compressive strength tests of cores are also presented in Table 1.

The nomenclature of specimens represents the condition of specimen whether it is reference specimen (without retrofitting), *Ref*, retrofitted specimen with NSM anchorage detail, *Ret1*, and ETS anchorage detail, *Ret2*. Ret1 stands for the retrofitting technique of NSM method for both outside and inside (anchorage) the joint region. Ret2 stands for the retrofitting technique of NSM and ETS method for outside and inside the joint region, respectively. Therefore, Ret1 and Ret 2 retrofitting techniques are designated with of NSM+NSM and NSM+ETS, respectively.

Table 1 Specimen details.

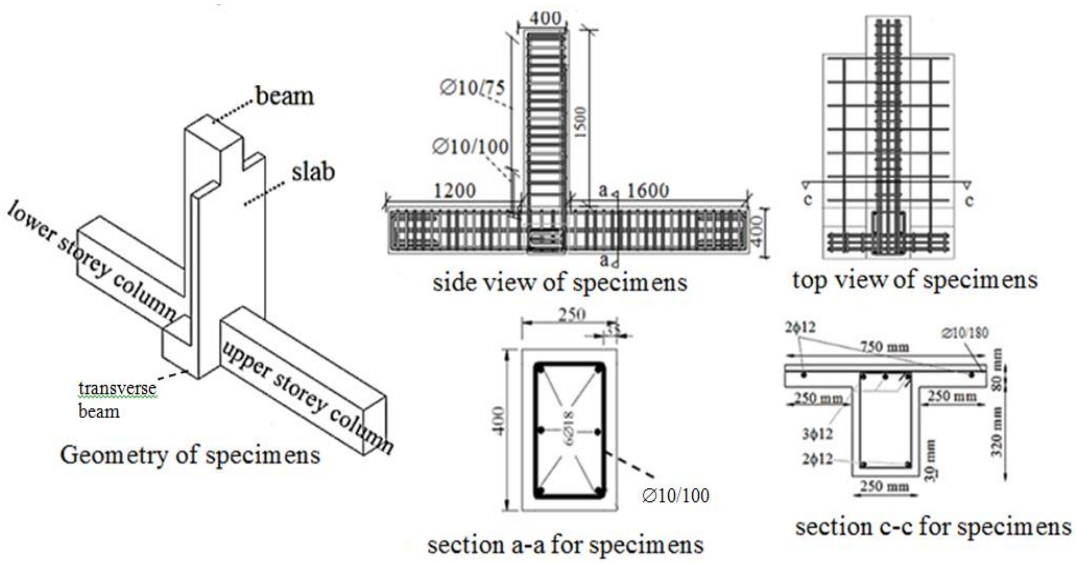

Figure 1 Geometry and reinforcement details of specimens (units in mm).

In the scope of the study, three full-scale exterior beam-column-slab sub-assemblages were constructed and tested, as shown in Figure 1. All sections of specimens were heavily reinforced against shear forces to ensure that they would be flexure-critical. The specimens were detailed based on the seismic design philosophy of weak beam-strong column both for reference and retrofitted specimens.

Table 2 presents the mechanical properties of three types of reinforcing bars used. In this table, f_y and ε_y are the yield stress and strain; ε_{sh} is the strain at the beginning of strain hardening; $f_{s\,max}$ and $\varepsilon_{s\,max}$ are the maximum stress and strain, and f_{su} and ε_{su} are the rupture stress and strain.

Table 2 Mechanical properties of reinforcing bars.

Reinforcement	Diameter (mm)	f_y (MPa)	ε_y	ε_{sh}	$f_{s\,max}$ (MPa)	ε_{smax}	f_{su} (MPa)	ε_{su}
∅18	18	474	0.0022	0.025	612	0.14	482	0.21

∅10	10	471	0.0022	0.027	611	0.13	533	0.20

Retrofit Design and Application

For retrofitting applications, a new type of material; CFRP ropes were utilized in longitudinal direction. This material was intentionally chosen due to its high flexibility and potential for better anchorage. It consists of a bundle of flexible CFRP fibers, which are held together by a thin net (El-Saikaly et al. 2014). According to the manufacturer's product data sheet, the nominal cross section area, ultimate rupture strain and tensile modulus of CFRP rope are 28 mm^2, 1.6% and 240 GPa. For bonding and impregnation, commercial epoxy adhesive with a tensile strength of 30 MPa, elastic modulus of 4500 MPa and ultimate elongation of 0.90% was used.

Two different techniques in terms of anchorage of CFRP ropes at the support region were utilized in the scope of the study. For the first anchoring type (Ret1), the FRP material was anchored inside the square grooves on the surface of the transverse beam next to the column side surface through typical NSM method. For the second anchoring type (Ret2), a recently developed method, named as embedded through-section (ETS) was utilized. For this, the CFRP rope was anchored by embedding inside pre-drilled circular holes throughout the bottom section of the upper story column. The retrofitting method between the tip of the beam and interface of joint region was identical for both retrofitted specimens. Typical NSM retrofitting technique was used in this region. Therefore, the retrofitting methods Ret1 and Ret2 were designated as NSM+NSM and NSM+ETS, respectively.

The details of grooves and retrofitting methods are presented in Table 3. In this table D is the diameter of circular holes drilled inside the joint region for ETS method, d_g is the square groove size, l_b is the bonded/development length, k is the groove size factor, d is the diameter of CFRP rope (6 mm). The holes in

ETS method were in the shape of circular since they were openned with a rotary hammer drill and they were bonded to whole perimeter unlike the three surface bonded square grooves openned for NSM method.

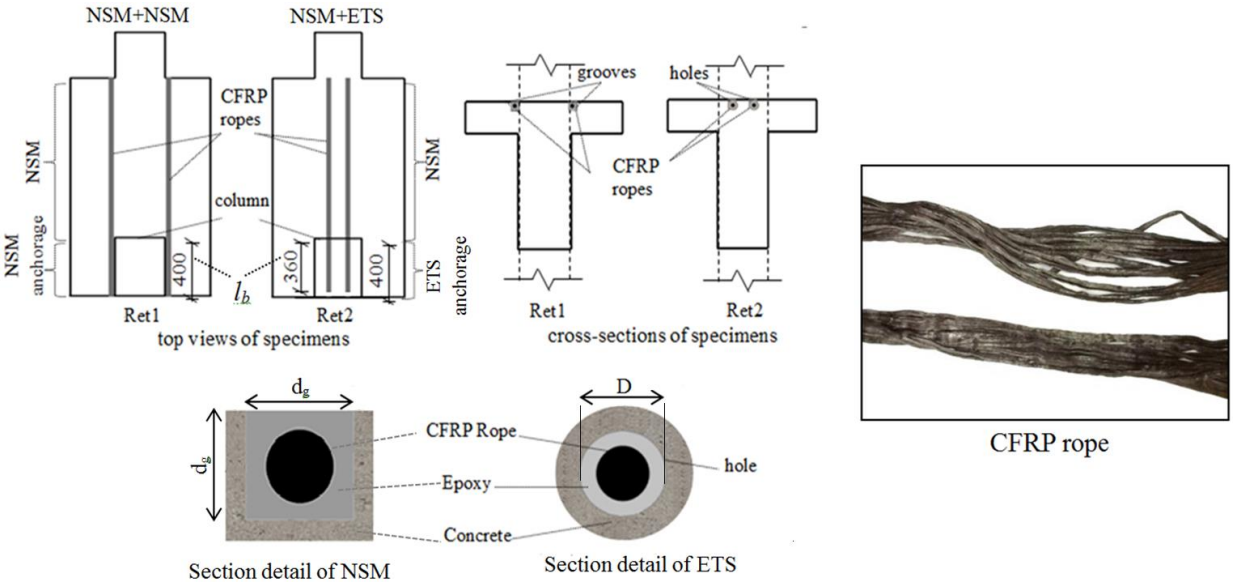

Figure 2. Schematic illustrations of retrofitting methods and and illustration of CFRP rope.

In this study, the theoretical bond strengths for these two different methods are determined according to the recommendations of De Lorenzis et al. (2002) Eqs. (1-3). According to these equations the debonding is foreseen to occur at the interface of the groove surface and epoxy.

$$\tau_{avlu} = P_{max} / (3\, d_g\, l_b) \tag{1}$$

$$P_{max} = E_{frp}\, \varepsilon_{frpu}\, A_{frp} \tag{2}$$

$$d_g = k\, d \tag{3}$$

$$\tau_{avlu} = P_{max} / (\Pi D\, l_b) \tag{4}$$

$$D = k\, d \tag{5}$$

In Eq. (1-3), P_{max} is the ultimate load, d_g is the square groove size, l_b is the bonded/development length, k is the groove-size-to-actual-rope-diameter-ratio, d is the diameter of CFRP rope (6 mm), D is the diameter of hole and τ_{avlu} the is average bond strength. E_{frp}, ε_{frpu} and A_{frp} are the elastic modulus (240 GPa), ultimate strain (rupture strain) (0.016) and cross-section area of FRP (28 mm^2), respectively. The FRP characteristics are provided by the manufacturer.

P_{max} is the ultimate load that corresponds to the rupture strength of CFRP rope [Eq. (2) and (4)]. For all retrofitted specimens P_{max} is constant and calculated as 107520 kN. The average bond strength for both retrofitted specimens (τ_{avlu}) is assumed as 5 MPa in order to allow a fair comparison between them [Eq. (1)]. ACI 440.2R-08 (2008) recommends to take the bond strength for NSM retrofitted members as 6.9 Mpa. Godat et al. (2012)'s study indicated that the bond strength of ETS retrofitted specimens varied between 8.4 and 15.1 MPa. Also, De Lorenzis et al. (2002)'s study revealed that the bond strength of specimens retrofitted with similiar surface preparation and reinforcement material with the proposed study were between 8.19 and 9.54 MPa. It can be concluded that the recommendation of the design code and findings of other studies point to an average bond strength over 5 MPa for NSM and ETS techniques. Therefore, it can be asserted that the assumption of the bond strength as 5 MPa enables to remain in conservative side according to the higher bond strength of literature studies and design code (ACI 440.2R-08 (2008)). For Ret1 and Ret2 specimens, the development lengths were equal to 400 and 360 mm. The difference between two development lengths stemmed from the presence of internal steel reinforcement for type2 retrofitted specimen. For the holes to be drilled inside the joint region at

the bottom of the column, Eq. (1) was modified to Eq. (4) consider the whole perimeter of the hole around FRP ropes bonded. The square groove sizes (d_g) and diameter of holes (D) were calculated according to the Eqs. (1) and (4), respectively (Table 3).

Retrofit application stages; (a) drilling the grooves of Ret1; (b) drilling the holes of Ret2; (c) top view of Ret2; (d) impregnation of CFRP ropes with epoxy paste; (e) insertion of CFRP ropes into drilled holes for Ret1; (f) insertion of CFRP ropes for Ret2; (g) final view of specimens retrofitted with Ret2; (h) final view of specimens retrofitted with Ret1.

Table 3 Details of retrofitted specimens.

Designation of specimen	Retrofitting Method	Anchorage Type	Amount of FRP (mm^2)	l_b (mm)	k	Groove (square) /Hole (circle) shapes & dimensions	
						Outside the joint region (mm)	Inside the joint region (mm)
Ret1	Type1 (NSM+NSM)	NSM	56	400 (67d)	3	Square d_g =18	Square d_g =18
Ret2	Type2 (NSM+ ETS)	ETS	56	360 (60d)	2.5	Square d_g =18	Circle D= 19

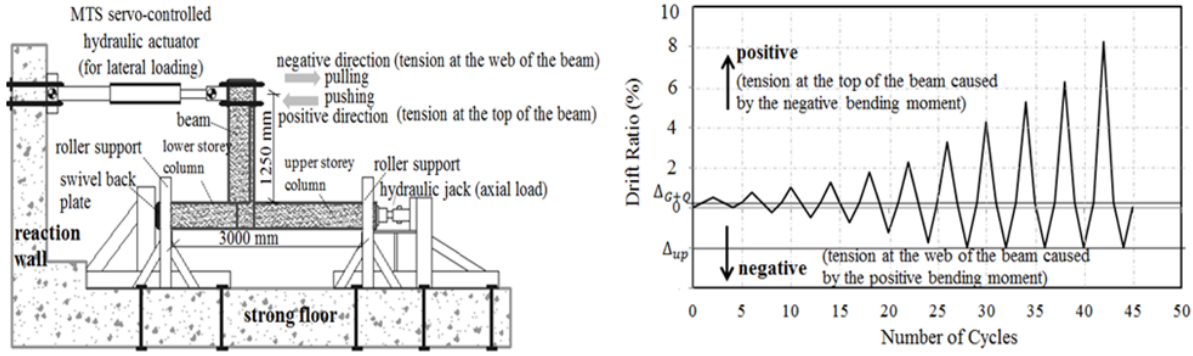
Test Setup

The specimens were tested with the beams in vertical position and columns in horizontal position. One half of the column represents the lower half of the upper-storey column and the other half of the column represents the upper half of the lower-storey column (Figure 4).

The specimens were supported by rollers at both ends of the columns which restrain vertical translation and release the rotation. The reversed cyclic lateral displacement/load was applied at the tip of the beam. During application of reversed cyclic lateral displacement/load, a constant axial load of 375 kN, which corresponds to the level of 0.1 f'_c bh was applied to columns by a hydraulic jack, where b and h are the width and depth of the column, respectively and f'_c is the compressive strength of core samples.

The main objective of the present study is to enhance the negative bending moment capacity of RC beam support regions which are to be subjected to both negative and flexural moments under reversed cyclic seismic actions. Before application of reversed cyclic displacement reversals, the support region of the beam was subjected to negative moment for representing the effects of vertical dead and live loads. Then additional displacement reversals were applied to the specimen such that the negative moment capacity of the beam is exceeded leading to non-linear inelastic deformations, where as the displacements were in the range of linear behaviour for positive moment for replicating most of the actual situations during seismic actions. Therefore, loads in pushing direction which lead to tension at beam webs were restricted to 60% of positive bending capacity. Each cyclic test was started with the initial drift ratio (Δ_{G+Q}) corresponding to beam displacements caused by the sum of dead and live loads. After reaching the initial displacement, a symmetrical pulling and pushing displacement controlled loading pattern which resembles seismic actions was applied to all specimens until reaching the pushing load which corresponded to 60% of the positive bending moment capacity of the beam. After this stage, the pulling displacements were increased according to predetermined target drift ratios, whereas the ultimate pushing drift ratios (Δ_{up}) which corresponds to 60% of the positive moment capacity were kept constant.

The applied loading pattern is illustrated in Figure 4.



test setup loading pattern

Figure 4 Test setup and loading pattern.

TEST RESULTS AND DISCUSSIONS

The failure of the reference specimen occurred due to concrete crushing in compression at large drifts after yielding of reinforcing bars in tension in pulling direction. Retrofitted specimens experienced failure due to the combination of CFRP rope debonding and partial rupture of some fibers (Figure 5). For both retrofitted specimens the debonding occurred at the interface of groove surface and epoxy. This findings coincided with the assumptions that the equations of De Lorenzis et. al (2002)'s study are based on [Eqs (1)-(5)]. Although these two different failure mode generally do not occur together (Sena Cruz and Barros 2004; De Lorenzis and Teng 2007; Bilotta et al. 2011), it is believed that this combination of failure stemmed from the characteristics of CFRP rope and approximately equal strengths of retrofitted specimens for debonding and rupture of CFRP ropes.

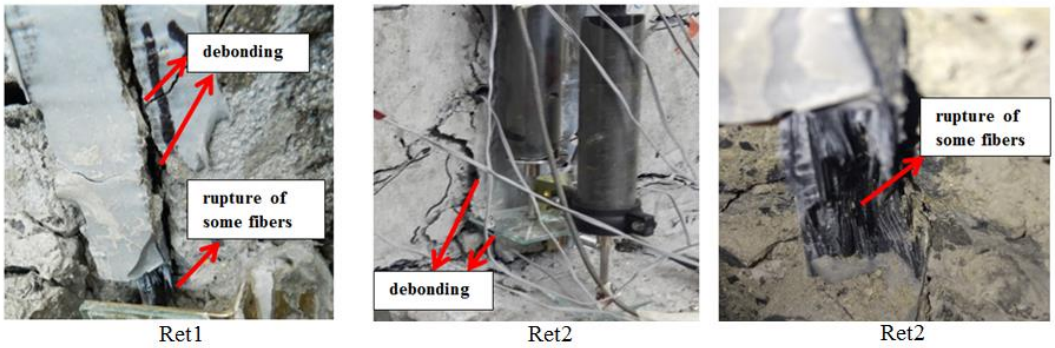


Figure 5 Failure of CFRP rope for retrofitted specimens.

Ret1 and Ret2 specimens were retrofitted with same amount of CFRP rope but, the results indicate that anchoring with ETS method (*Ret2*) is not as efficient as anchoring with NSM method (*Ret1*) in terms ductility and load carrying capacity.

For Ret1 specimen, the maximum load carrying capacity (103kN) was observed at drift ratio of 2%. At this drift ratio, the reference and Ret2 specimens corresponding capacities are 85 and 83 kN, respectively. Therefore, it can be asserted that the load carrying increase for Ret1is equal to 21% when compared with the reference specimen. For Ret2 specimen, the maximum load carrying capacity (89 kN) was observed at drift ratio of 1.2 %. At this drift ratio the reference and Ret1 specimens corresponding capacities are 80 and 91 kN, respectively. Therefore, it can be asserted that the load carrying increase for Ret1is equal to 11% when compared with the reference specimen. The enhanced strengths could not be sustained after these drift ratios. However, Ret1 and Ret2 experienced higher load carrying capacities until the failure of CFRP rope anchorages at the drift ratios of 2.6 and 1.3%, respectively (Table 4).

Table 4 Development of damage.

Specimen	First flexural crack		First yielding of longitudinal bar		Maximum strength			Failure of CFRP rope		Crushing of Concrete	
	Load (kN)	Drift Ratio (%)	Load (kN)	Drift Ratio (%)	Load (kN)	Drift Ratio (%)	Load Increase (%)	Load (kN)	Drift Ratio (%)	Load (kN)	Drift Ratio (%)
Ref	31	0.13	72	0.4	90	9	-	-	-	81	3.3
Ret1	30	0.09	61	0.5	103	2	21	81	2.6	103	3.4
Ret2	47	0.3	57	0.5	89	1.2	11	80	1.3	-78	3

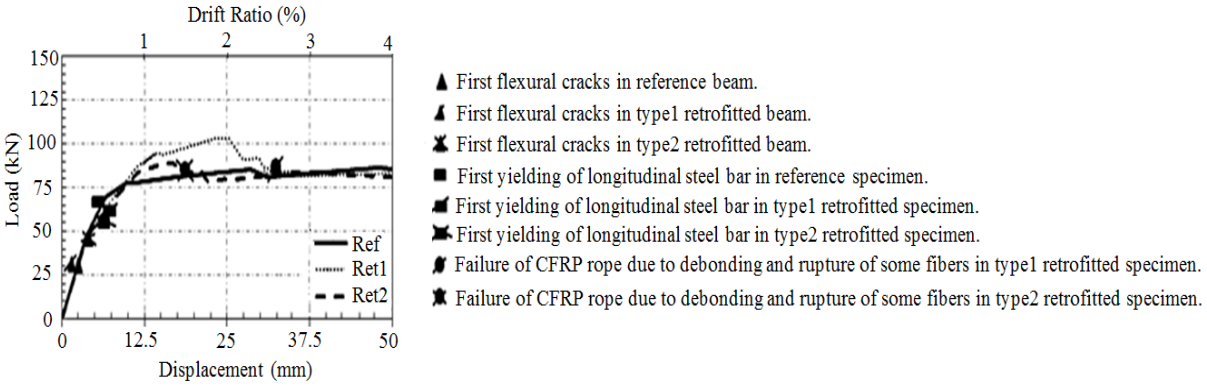

Figure 6 Envelopes of lateral load-drift ratios and development of damage.

The outcomes of the study which are presented in Table 4 and Figure 6 indicated that specimens retrofitted with NSM anchoring method (*Ret1*) achieved a remarkable enhancement in flexural capacity (21%) at drift ratio of 2%, whereas, specimens retrofitted with ETS technique (*Ret2*) achieved lower carrying capacity increase (11%) at lower drift ratio of 1.2% than Ret1. Therefore, it can be asserted that specimen retrofitted with NSM anchorage detail (*Ret1*) achieved higher load carrying capacity increase and maintained the increase until higher drift ratios (up to 2%) compared to the specimen retrofitted with ETS anchorage detail (*Ret2*).

The reason of the different performance results for Ret1 and Ret2 specimens is believed to be stemming from the challenging task of anchoring the CFRP rope within a length of 360 mm in a drilled holes for Ret2. Therefore, in order to examine the cross section of ETS anchorage method in detail, core samples within the area of the application of anchorage were extracted in horizontal direction. The samples indicated that specimen retrofitted with Ret2 have some deficiencies in terms of unimpregnated fibers and voids (Figure 7) which was not the case for Ret1. Therefore, it can be asserted that embedment CFRP rope material within a long length such as 360 mm, may lead to application faults and inadequate results.

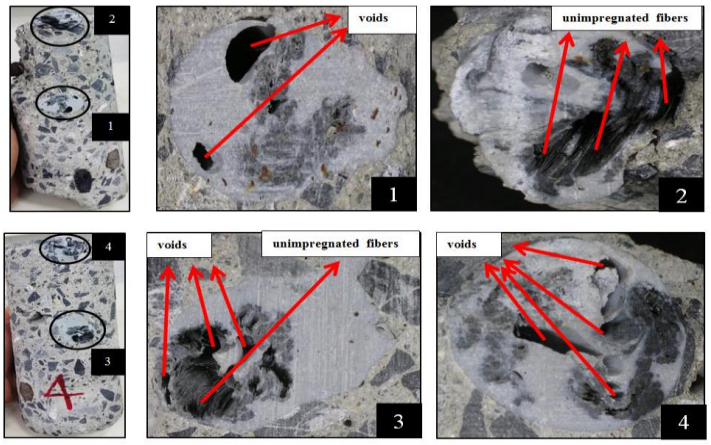

Figure 7. Core samples and images for specimen Ret2 and view of interfaces of concrete, CFRP rope and epoxy.

CONCLUSIONS

The present experimental study is conducted to investigate the effectiveness of two different anchoring techniques used during FRP retrofitting of beam support sections for enhancement of the flexural strength with CFRP ropes under reversed cyclic loading conditions. Proposed techniques in this paper consist of two different methods in terms of anchoring the CFRP ropes to the support regions. For both retrofitting types, NSM method was utilized outside the joint region. For the first retrofitting type, Ret1 (*NSM+NSM*), NSM method with square grooves was used for the anchorage of CFRP rope material on the slab next to the column side surface inside the joint region. For the second retrofitting type, Ret2 (*NSM+ETS*), embedment of CFRP rope material within the pre-drilled circular holes opened with rotary hammer drill throughout the bottom section of the upper storey column was used for anchorage of CFRP ropes inside the joint region.

Specimen retrofitted with NSM anchorage detail exhibited superior behaviour than the specimen retrofitted with ETS anchorage detail. It experienced the ultimate load carrying capacity increase (21%) at drift ratio of 2% and the failure of CFRP rope anchorage occurred at relatively higher drift ratio (2.6%). On the other hand, specimen retrofitted with ETS method experienced its ultimate load carrying capacity increase (11%) at drift ratio of 1.2% and the failure of CFRP rope anchorage occurred at quite lower drift ratio (1.3%) due to the failure of CFRP rope anchorage.

After physical investigation it was figured out that specimen retrofitted with ETS anchorage method had some deficiencies in terms of impregnation of fibers and proper filling of the anchorage hole. These deficiencies are attributed to the application problems due to the difficulty of embedding FRP ropes within an anchorage hole of 360 mm length.

Further studies should be carried out in order to better understand the behavior of CFRP ropes anchored in the joint either with NSM or ETS type details. Since this study is one of the first studies using this new form of FRP reinforcement, further studies should be carried out in order to support and improve the findings of this study.

ABSTRACT

An experimental investigation was conducted in this study on axially loaded square hollow section (SHS) slender columns retrofitted by carbon fiber reinforced polymer (CFRP). A total of seven specimens with identical cross section dimensions and raw material properties were compressed between pinned ends to identify the influence of the CFRP, in which six specimens were retrofitted by the CFRP. The effects of many influential factors including different layers of the CFRP, retrofitting directions of the CFRP and retrofitting sequences of the CFRP on the behaviour of the CFRP strengthened SHS slender columns were carefully evaluated. The column strengths obtained from the experimental investigation are compared with the design strengths calculated using the design equations given in the British Standard (CIRIA) and the equations modified based on the section conversion method proposed by Canadian Standard (CAN/CSA-S16-01). It is shown from the comparison that the ultimate strengths of the SHS slender columns were enhanced by retrofitting with the CFRP. The retrofitting directions of the CFRP in the longitudinal directions were found to have a great influence on the ultimate strengths of the CFRP strengthened SHS slender columns. Furthermore, a correction factor (β_c) is proposed in this paper for the stability of the CFRP retrofitted SHS slender columns under axial compression.

INTRODUCTION

Steel construction has been widely manufactured with the universalized conventional material. Steel can be applied to various fields of construction, such as civil engineering, petrochemical industry and many other relevant fields. However, the steel structures inevitably have some imperfections and damages to some extent. In order to ensure a good environment for steel structures and prevent them from failure, an alternate approach needs to be urgently proposed to upgrade and repair steel structures (Yue *et al*. 2009). The carbon fiber reinforced polymer (CFRP) was developed as a good choice. The CFRP is a composite material mixed by high-performance carbon fiber with a certain percentage resin and other materials using the processing technology. Compared with the traditional retrofitting methods, such as bolting or welding steel plates to the damaged components, the CFRP has many advantages including light weight, high strength-to-weight ratio and excellent resistances to fatigue and corrosion (Li 2011). The CFRP has a broad application in the retrofitting fields.

CFRP sheets have been successfully demonstrated on concrete structures (Ma 2011). However, there is quite limited research on retrofitting steel structures using CFRP sheets. Most of scholars in this field focused on slender and stub tubular columns strengthened by composite fibers (Shatt and Fam 2006; Bambach 2009; Gao 2013), and different shapes of cross section including square hollow section (SHS) and circular hollow section (CHS) (Haedir and Zhao 2011; Sundarraja *et al*. 2014). It was found that the longitudinal CFRP layers provided better confinement for slender specimens, whereas the transverse direction perpendicular to the longitudinal fibers was the optimum for stub tubular columns (Shatt and Fam 2006). For CHS tubular columns, it was found that the relationship between the number of layers and the ultimate capacity was proportional (Gao 2013).

Whilst there are some researches about elucidating the efficacy of applying CFRP sheets to compression columns, limited study on full-scale experiment on tubular specimens under axial loading has been examined. The efficient theoretical system has also been in an immature state. Therefore, the investigation on axially compressed full-scale columns strengthened by CFRP can satisfy the current design requirement.

In order to provide theoretical support for the upgrade of Chinese Code for Reinforcement Design of Steel Structures, an experimental program has been carried out to investigate the reinforcement effect of CFRP sheets of two different fiber orientations, with two or four CFRP layers. The influential factors include the number of

CFRP layers (two and four layers), the fiber orientation (transverse and longitudinal), and the arrangement of CFRP (transverse fiber only, longitudinal fiber only, and transverse fiber followed by longitudinal one). Accordingly, the maximum enhancement can be gained by comparing different types of strengthening. Based on the British Standard (CIRIA) (Cadei *et al*. 2004) and Canadian Standard (CAN/CSA-S16-01), this study is intended to integrate test values with equations in relevant design codes, and modify the theoretical equations used for ultimate loads of components retrofitted by CFRP under axial compression.

EXPERIMENTAL PROGRAM

Theoretical Foundation

The section conversion method in British Standard (CIRIA) and Canadian Standard (CAN/CSA-S16-01) is applied to calculate the cross-sectional area of specimens strengthened by CFRP under axial compression. The cross-sectional area and the moment of inertia for the steel section have been replaced by converted sectional area and moment of inertia, respectively. The equations of converted section are given as follows:

$$A_t = A_s + \sum_{i=1}^{N} \left(\frac{E_{f_i}}{E_s} A_{f_i} \right) \tag{1}$$

$$I_t = I_s + \sum_{i=1}^{N} \left(\frac{E_{f_i}}{E_s} I_{f_i} \right) \tag{2}$$

where A_t and I_t are the converted cross-sectional area and moment of inertia, respectively; A_s, I_s and E_s are the cross-sectional area, moment of inertia, and Young's modulus of the steel section, respectively; A_{fi} and I_{fi} are the cross-sectional area and moment of inertia of the ith CFRP layer, respectively; E_{fi} is the effective Young's modulus in the longitudinal direction of the column for the ith CFRP layer; N is the number of CFRP layers.

Then the slenderness ratio of composite specimens based on the modified cross section is given by Eq. 3:

$$\lambda_c = \frac{L_0}{i_t} = \frac{L_0}{\sqrt{I_t/A_t}} \tag{3}$$

where λ_c is the slenderness ratio of the composite specimens; L_0 is the effective length of retrofitted SHS columns; i_t is the radius of gyration of converted sections.

After that, the ultimate strengths of SHS columns can then be introduced. Although the reinforcement of components under axial compression has been mentioned in British Standard (CIRIA) and Canadian Standard (CAN/CSA-S16-01), the study on axially compressed specimens is very limited (Liu 2007). The design equation for the ultimate capacity of retrofitted axially compressed specimen is still unavailable. With reference to the theories above, a correction factor β_c reflecting the effect on reinforcement of axially compressed members is introduced. The modified equation is given as follows:

$$\frac{N}{\beta_c \varphi_c A_t} \leq f \tag{4}$$

where N is the ultimate stabilizing capacity of retrofitted specimens under axial compression; β_c is a correction factor considering the impact of orientations of CFRP fiber, whose value is estimated by experimental analysis; φ_c is the stabilizing factor of compressed members after reinforcement, which is obtained from the current Chinese Code (GB 50017-2003) according to the slenderness ratio λ_c of composite members after retrofitting; f is the design strength of steel, determined according to the current Chinese Code (GB 50017-2003).

Test Setup and Instrumentation

Seven slender SHS columns were tested in the experiment, one of which was unreinforced for comparison, while the other six specimens were retrofitted by CFRP sheets using different numbers of CFRP layers, orientations of CFRP fiber and fiber configurations of CFRP. The nominal length of all specimens is 3000 mm, with the identical SHS cross section of 150×150×10 mm. The details of specimens are shown in Table 1.

Table 1 Details of test specimens

Specimen	B/mm	L_0/mm	t/mm	Layers of CFRP	Arrangement of CFRP
A-0	150	3000	10	0	—
A-2L	150	3000	10	2	2L
A-2T	150	3000	10	2	2T
A-1T1L	150	3000	10	2	1T1L
A-4L	150	3000	10	4	4L
A-4T	150	3000	10	4	4T

A-2T2L	150	3000	10	4	2T2L

Note: 2L means two longitudinal CFRP layers; 2T means two transverse CFRP layers; 1T1L means one transverse CFRP layer followed by one longitudinal CFRP layer.

Test setup is shown in Figure 1. In order to record and analyze the strains of SHS columns, the strain gauges were pasted on the surface of steel columns and CFRP sheets, while the displacement transducers were positioned on the relevant places (Shi *et al*. 2013). The locations of strain gauges and displacement transducers on steel tube and CFRP sheets are shown in Figures 1-3.

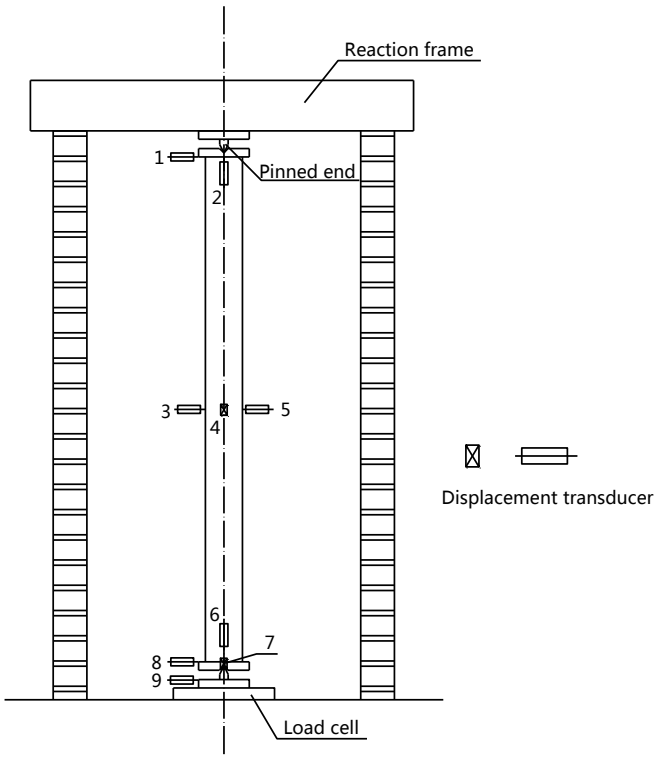

Figure 1 Test setup

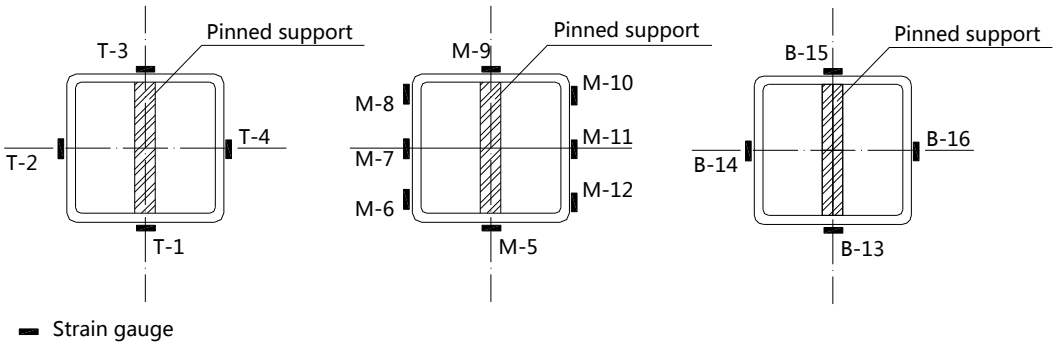
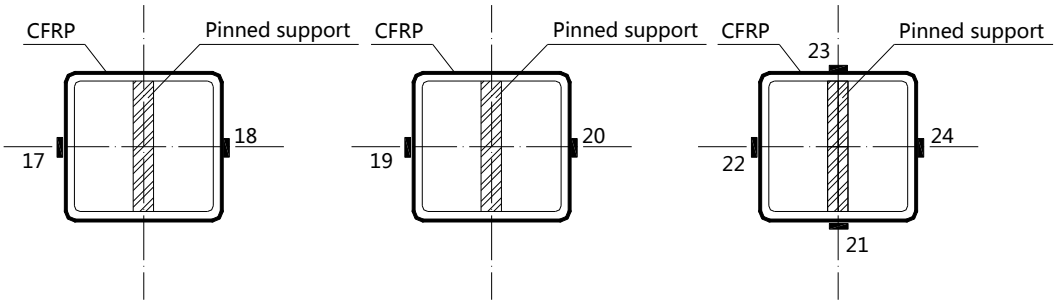


(a) Top end of column (b) Middle of column (c) Bottom end of column

Figure 2 Location of strain gauges on steel tube



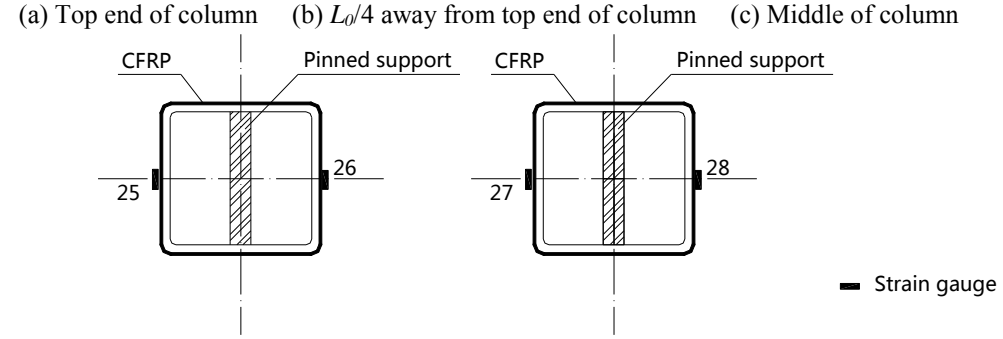


Figure 3 Location of strain gauges on CFRP

First, each specimen was preloaded to 100 kN for several times to calculate the loading eccentricity (Wang *et al*. 2014). After that, the axial load was formally applied to the specimens. The data acquisition instrument was used to record the readings of strain gauges and displacement transducers until the failure of specimen.

RESULTS AND ANALYSIS

Failure mode

All specimens failed by the overall bucking of the column combined with the delamination of CFRP at the mid-length of the column, as shown in Figure 4.

(a) Overall bucking of column (b) Delamination of CFRP at the mid-length of column

Experimental Analysis

The initial eccentricities of seven specimens are shown in Table 2, where v_1, v_2 and v_3 are the initial geometrical eccentricities on the cross section of L_0/4, L_0/2 and 3L_0/4 away from top end of column, respectively; v_0 is the maximum of v_1, v_2, v_3; e_{0t} and e_{0b} are the initial loading eccentricities on the top and bottom end of column, respectively; e is the assembly initial eccentricity, $e=v_0+(e_{ot}+e_{0b})/2$; e/L_0 is the ratio related to the assembly initial eccentricity.

Table 2 Initial eccentricities of test specimens

Specimen	v_1/mm	v_2/mm	v_3/mm	v_0/mm	e_{0t}/mm	e_{0b}/mm	e/mm	e/L_0
A-0	1.5	2.0	2.5	2.5	0.38	1.78	3.58	1.19‰
A-2L	1.0	1.5	2.0	2.0	-1.86	4.38	3.26	1.09‰
A-2T	2.5	2.5	1.5	2.5	10.15	-2.95	6.10	2.03‰
A-1T1L	4.5	4.0	3.0	4.5	3.28	2.43	7.31	2.44‰
A-4L	1.0	0.5	0.5	1.0	7.92	-2.53	3.70	1.23‰
A-4T	-1.5	-2.0	-2.5	-2.5	-3.75	-0.26	-4.51	1.50‰

A-2T2L	1.0	2.5	2.0	2.5	-6.35	-7.35	-4.35	1.45‰

Seven specimens were generally subjected to brittle failure. The experimental and analytical values are shown in Tables 3 and 4, respectively, where L_0 is the effective length of columns, e is the value of initial eccentricity, P_u is the experimental ultimate capacity, δ is the displacement in the middle of the column, A_t and I_t are the converted cross-sectional area and moment of inertia, respectively, λ_c is the slenderness ratio of composite specimens, ϕ_c is the resistance factor of composite specimens, and P is the analytical ultimate capacity. Comparing the effects of reinforcement in different ways, the most pronounced effect occurred on the specimens retrofitted by longitudinal layers of CFRP, in which the ultimate capacity of two layers in longitudinal direction was improved by 30.9%, followed by bonding transverse layers prior to longitudinal ones. And the minimal effect occurred on the specimen strengthened by transverse layers only. It is different from the previous study on stub columns that the transverse layers have the most pronounced effect. Further studies on the effect of CFRP are still required. The P-δ curves of test specimens strengthened by different layers of CFRP are shown in Figures 5 and 6.

Table 3 Experimental ultimate capacity of test specimens

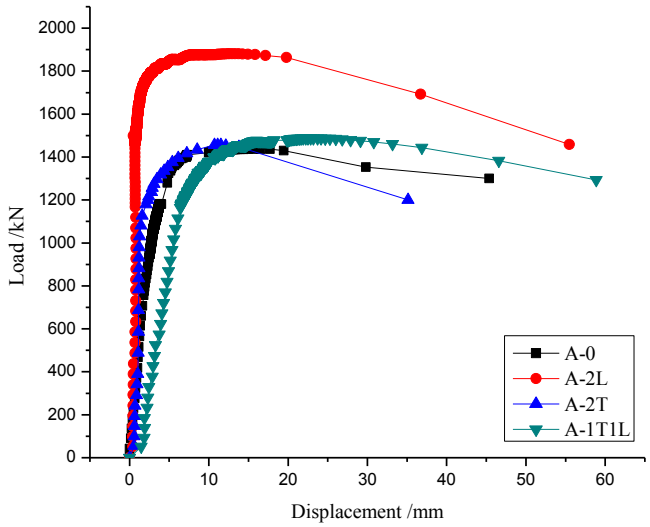

Figure 5 P-δ curves of test specimens strengthened by two layers of CFRP

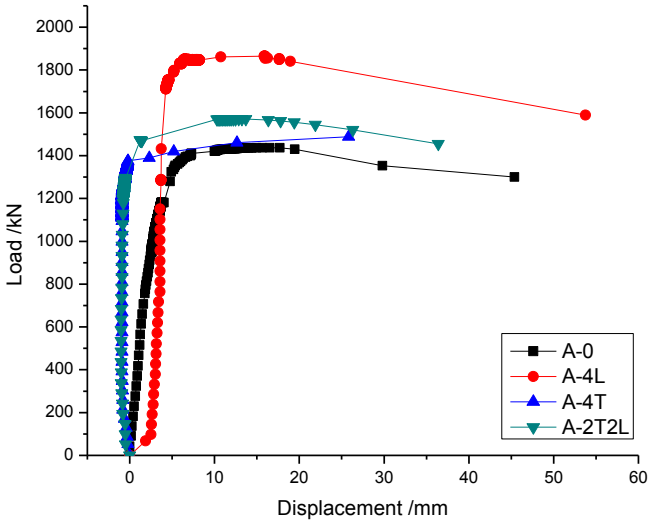

Figure 6 *P*-δ curves of test specimens strengthened by four layers of CFRP

Comparing Figures 5 and 6, the curves show that the best effect of reinforcement is on specimens A-2L and A-4L, whose ultimate capacity was increased by 30.9% and 29.7%, respectively. It indicates that the strengthening method of longitudinal layers is the most effective, whereas the other two methods can merely increase the ultimate capacity by less than 10% (transverse layers followed by longitudinal ones and transverse layers only). The reinforcement effect of transverse layers on SHS columns was found in this paper to be different from the conclusions given in the research (Gao *et al*. 2013) that the transverse layers have a better reinforcement effect on CHS columns.

Furthermore, with the same orientation of CFRP layers (Specimens A-2L and A-4L), the reinforcement effect on SHS columns cannot be improved with the increase of CFRP layers. The strength enhancement in specimens A-2L and A-4L are almost the same even though twice amount of CFRP was used for specimen A-4L. It may attribute to the delamination of outer CFRP layers that cannot cooperate well with SHS columns. Therefore, the tensile strength of CFRP cannot be fully utilized.

It can also be summarized that, according to curves in Figures 5 and 6, the ultimate capacity of specimen A-2T2L is much lower than that of specimen A-2L, although the same amount of longitudinal CFRP was used and two additional transverse layers were further applied for specimen A-2T2L. According to the experimental results, the buckling shape of SHS columns is one side bulked outwards, and the other side bulked inwards. It makes the CFRP boned on the inward bulking side cannot synergize well with SHS columns, thereby weakened the reinforcement effects.

Finally, the curves of specimens A-2L and A-1T1L in Figure 5 indicate that the strength enhancement of specimen strengthened by longitudinal CFRP layers is much higher than that of the specimen retrofitted by transverse CFRP layers prior to longitudinal ones, although the same number of CFRP layers were used. It may result from the transverse CFRP layers boned on the SHS columns, which weakened the reinforcement effects of the longitudinal CFRP layers.

From the analysis above, it was found that the longitudinal CFRP layers can remarkably enhance the ultimate capacity of SHS columns compared to the transverse CFRP layers.

Correction Factor β_c

Based on Tables 3 and 4, considering the deviations of experimental and analytical values, the optimal reinforcing method is to strengthen SHS columns with longitudinal CFRP layers only. Therefore, this retrofitting method is intensively recommended. Furthermore, two other ways of reinforcement – transverse CFRP layers only and transverse CFRP layers prior to longitudinal CFRP layers are inadvisable choices in the practical applications. A correction factor β_c of the stabilizing capacity in Eq. 4 can be preliminarily determined as β_c=1.05. Further researches on this aspect are still required.

CONCLUSIONS

This paper presents an experimental investigation on the ultimate capacity of CFRP retrofitted steel SHS columns under axial compression. Accordingly, it can be concluded that the effect of strengthening has an inseparable relationship with the orientation of CFRP, among which the most effective one is the reinforcing method of two longitudinal CFRP layers. It can also be concluded that there is no significant enhancement on the ultimate capacity by using different numbers of CFRP layers in the same fiber orientation. Furthermore, the transverse CFRP layers boned on the SHS columns have detrimental influence on the reinforcement effects of the longitudinal CFRP layers. Comparing the experimental values with the equations given in British Standard (CIRIA) and Canadian Standard (CAN/CSA-S16-01), a correction factor β_c of stabilizing capacity in different situations is proposed.

ACKNOWLEDGEMENTS

This research work was carried out to support the update of Chinese Code for Reinforcement Design of Steel Structures. The tests were conducted in Anhui Key Lab on Structure and Material of Civil Engineering at Hefei University of Technology. The support provided by the laboratory staff is gratefully acknowledged.

ABSTRACT

The use of Glass Fibre-Reinforced Polymer (GFRP) composite materials as reinforcement for concrete structures to overcome corrosion problems has been growing. Past Canadian applications are dominated by bridge decks and car parks where de-icing salts are used. Other applications include coastal structures and structures aiming for improved durability. Our research aimed to examine the practicality of using GFRP bars as reinforcement in concrete compression members. Twenty-four concrete columns reinforced with either steel or GFRP were loaded in compression until failure, with ultimate compressive strengths and horizontal displacements of the bars recorded. The results indicate that the use of GFRP bars as reinforcement in concrete compression members is technically viable, with GFRP reinforced columns yielding almost the same capacity as those reinforced with equal areas of steel. Incorporation of extra GFRP stirrups was found to improve the capacity in bending of the longitudinal GFRP reinforcement. Cost comparisons have also been completed to ensure the use of GFRP reinforcement is economically viable. The research concluded that reinforcing concrete columns with GFRP bars is an attractive option when life span and/or durability are of high priority. The research was followed by the first design and construction of reinforced concrete compression members utilising GFRP in Australia. This was done at the Dundas Point Boardwalk on the Swan River in Applecross, Western Australia, completed in 2014. Ongoing research will initiate in 2015 at UWA to investigate GFRP subject to combined bending and axial stressing.

INTRODUCTION

Background and Motivations

Fibre Reinforced Polymers (FRP) are composite materials used to strengthen concrete structures. They are made of fibres of a particular material selected, embedded in a polymeric resin. The most common fibres used in FRPs are glass, carbon or aramid. FRPs can come in woven sheets, which attach to the outside of reinforced concrete structures to offer strengthening, usually for remediation purposes. FRPs are less commonly produced as reinforcing bars, instead of steel reinforcement.

Advantages of FRP bars include; having high tensile strength, being corrosion resistant, nonmagnetic and lightweight with low thermal and electrical conductivity. This suite of characteristics is useful in many situations. FRP bars are well suited for use in corrosive environments, in structures required to have a very long design life, in hospitals near MRI machines, for example, and provide easy workability because they are so lightweight.

Disadvantages of FRP bars include; no yielding before failure, low transverse strength, low modulus of elasticity and possible durability issues of glass fibres in alkaline environments. These characteristics need to be understood with guidelines to manage risk associated with these properties in concrete.

In 2001, the American Concrete Institute (ACI) released their first standard detailing recommendations of the use of FRP bars in reinforced concrete (RC). “Guide for the Design and Construction of Structural Concrete Reinforced with FRP Bars” (1) is the most current standard and was published in February 2006. ACI Committee 440 has chosen not to offer recommendations on the use of FRP bars in compression members due to the lack of experimental data.

Objectives

This study aims to further the knowledge of Glass Fibre Reinforced Polymer (GFRP) bars used to internally reinforce concrete compressive members. An experimental program using concrete columns reinforced with GFRP bars was designed to examine the effect GFRP bars has on the compressive strength and failure mode of the columns, and gain data on the displacements of the reinforcing bars themselves. A steel reinforced set of columns of matching size was used for comparison. The overall target was to determine if the use of GFRP bars is practical, and to give accurate guidelines as to what precautions, if any, should be taken when using GFRPs in reinforced concrete compressive members.

Corrosion tests were performed on steel bars and GFRP bars in several different saline solutions to determine if GFRP bars were subject to corrosion in a similar way to steel. The solutions included, distilled water, sea water and three salt water solutions varying in strength (10%, 20% and 32% weight ratio of salt to water). The two steel and GFRP bar types were immersed in the solutions for an extended period and weight loss due to corrosion measured.

GFRP LITERATURE REVIEW

GFRP Bars

Compression members reinforced with GFRP bars are limited to the research laboratories as not enough information has been recorded to allow guidelines or standards to be compiled. The testing of GFRP no. 15 (15mm diameter) bars under compression found that the ultimate compressive strength is approximately equal to 50% of the ultimate tensile strength, and the modulus of elasticity in compression can be considered approximately equal to the modulus of elasticity in tension (3). Alsayed, Al-Salloum, et al. (2) tested full size concrete columns under concentric compression to investigate the effect of replacing steel reinforcement with equal amounts of GFRP reinforcement. The axial capacity of the GFRP reinforced columns was 13% less than the steel reinforced equivalent.

GFRP Ties

Previous literature has evaluated the use of GFRP ties in place of steel ties to assess their effect on the compressive capacity and mode of failure on reinforced concrete columns. Research around GFRP ligatures is dominated by stirrup spacing, which evidently plays a part in the failure mode of compressive members.

Alsayed, Al-Salloum, et al. (2) used GFRP ties in their concentrically loaded columns and deduced that it reduced the axial capacity by only 10% compared to columns reinforced with traditional steel ties. Furthermore, they concluded that the replacement of the steel ties with GFRP ties had no influence on the load-deformation of the column up to approximately 80% of ultimate capacity.

EXPERIMENTAL DESIGN

Column Parameters

The reinforced column sample design had to be of such a size and strength to satisfy certain criteria. The columns need to be:

- long enough to be considered ‘full size’
- short enough to fit comfortably into the testing machine
- deemed to be slender under conditions set out in AS 3600 (4)
- capable of withstanding no more than 2000kN
- designed in accordance with AS 3600 (4)
- and to have ties of appropriate shape and size to be manufactured

Using the Rectangular Stress Block method and modeling columns of different dimensions, reinforcement arrangements and concrete strengths in analysis software to gain an estimate of the column capacities, the dimensions of the sample columns were defined as 160mm x 160mm x 1500mm. It was also decided that four longitudinal bars would be used to reinforce the columns. In addition, two batches of concrete were to be considered. The batches were to have strengths in the range of 40MPa and 60MPa.

Calculations were carried out on all reinforcement arrangements to ensure columns satisfied all conditions of AS 3600 (4) Section 10.

A circular tie of 100mm in diameter was selected. This gave cover to tie reinforcement of 30mm and cover of 45mm to the longitudinal reinforcement.

Reinforcing Materials

GFRP Reinforcement

The ordered materials included 9.53mm diameter GFRP bars in 3 metre lengths and 100mm diameter circular ties using 6.35mm diameter GFRP bars.

The properties of the GFRP bars considered for use in this research are presented in Table 1 below.

Table 1 GFRP Bar Properties.

Bar Size (inches)	Nominal Diameter (mm)	Guaranteed Tensile Strength (MPa)	Modulus of Elasticity (GPa)
#2	6.35	840	43
#3	9.53	750	43
#4	12.70	685	43

Steel Reinforcement

The University of Western Australia Structures Laboratory supplied the steel reinforcing bars used in the columns. All bars used were N-bars and their properties can be seen in Table 2 below.

Table 2 Steel Bar Properties.

Nominal Diameter (mm)	Guaranteed Tensile Strength (MPa)	Modulus of Elasticity (GPa)
6	500	200
10	500	200
12	500	200

It was decided that 6mm wide cuts of 100mm diameter steel pipe would be used as a substitute for steel ligatures. The ties are needed only to provide restraint to the longitudinal reinforcing bars.

Reinforcement Arrangement

There are four different reinforcing arrangements tested in this experiment. They were carefully chosen to give results so that the following points could be investigated.

- How GFRP reinforced columns compare to steel columns when loaded in a manner to create theoretical tensile capacity in the reinforcing.
- How GFRP reinforced columns compare to steel columns with the same nominal volume of reinforcing.
- The effect of tie spacing on the capacity and failure mode of GFRP reinforced columns.

Naming Convention

As there are four reinforcement arrangements and two concrete batches, there are eight different column types considered. Their naming convention is detailed in Table 3.

Table 3 Column Naming Convention.

Column Name	Longitudinal Reinforcement	Tie Spacing	Concrete Ordered
FRP Max 50	9.53mm GFRP	Maximum (150mm)	50 MPa
FRP Min 50	9.53mm GFRP	Minimum (75mm)	50 MPa
10mm Steel 50	10mm Steel	Maximum (150mm)	50 MPa
12mm Steel 50	12mm Steel	Maximum (150mm)	50 MPa
FRP Max 65	9.53mm GFRP	Maximum (150mm)	65 MPa
FRP Min 65	9.53mm GFRP	Minimum (75mm)	65 MPa
10mm Steel 65	10mm Steel	Maximum (150mm)	65 MPa
12mm Steel 65	12mm Steel	Maximum (150mm)	65 MPa

Three columns of each column type were cast. For example the FRP Max 50 columns where named FRP Max 50 (1), FRP Max 50 (2) and FRP Max 50 (3). This means that each group can be easily referred to and each individual column has a distinct name.

METHODS AND PROCEDURES

Concrete Cylinder Compression Tests

The concrete cylinders cast and prepared were tested in compression using the Baldwin machine at the University of Western Australia Concrete Laboratory. The Baldwin machine is a hydraulically operated machine where load is applied by the upwards displacement of the steel table. The load was increased until failure occurred so that a maximum load could be recorded and the failure mode noted. The load and table displacement were recorded with a computer program.

Column Compression Tests

The 24 reinforced concrete columns were tested in compression using the Amsler machine at the University of Western Australia Structures Laboratory. The Amsler machine is a hydraulic operated apparatus. The machine works by displacing the top steel plate downwards to apply load and is capable of delivering up to 2000kN of load.

A steel plate is used to create a slightly eccentric load. This was done to differentiate from the tension and compression sides of the column. The 160mm by 160mm steel plate was designed to be able to line up with each side of the column and the welded semi-circular bar would be precisely 4mm off centre. This ensured that the same eccentricity was placed on each column to provide consistent results.

Strain gauges were attached to the centre of the tension side of the longitudinal reinforcing bars and waterproofed prior to casting the columns. The strain gauges were connected to an amplifier using quarter bridge cables.

The column was loaded at a rate of approximately 5kN per second until failure of the column occurred.
The results of reinforcement displacement, column load and table displacement were recorded into a computer program via a series of data points. These data points can then be used in conjunction with the defects noted and failure modes exhibited to analyse the performance of the reinforcement.

Figure 1 Left: Column in Amsler Machine. Centre: Steel Plate. Right: Ruptured GFRP Bar and Tie.

Corrosion Tests

Corrosion testing was carried out on both steel reinforcement and GFRP reinforcement. Samples of each bar were submerged in distilled water, sea water and three salt water solutions. The measurements of the salt water solutions prepared are shown in Table 4.

Table 4 Salt Water Solutions.

Salt Solution No.	Weight of Salt (g)	Weight of Water (g)	Percentage of Salt in Solution (%)
1	15.2	150	10.1
2	29.7	150	19.8
3	48.6	150	32.4

The samples were weighed prior to testing. The samples were left for 45 days. The bars were then inspected for rust before being thoroughly cleaned and weighed again to measure weight loss.

RESULTS AND DISCUSSION

Concrete Strength

Two batches of concrete were required to cast the 24 columns. Readymix concrete was necessary to ensure the same concrete properties were obtained for each of the specimens, therefore giving reliable results. The slump of both mixtures was ordered at 80mm. As 0.8 cubic metres of each batch was needed, it was clear that mixing the concrete by hand would not be time or cost effective.

The concrete columns were to be cured for 14 days. This meant that an estimation of the standard 28 day strength had to be made so as to receive the strength wanted at 14 days.

The concrete for testing was prepared by casting four, 100mm diameter, 200mm long cylindrical samples for each batch. These were tested in compression after 14 days, the same curing time as the concrete columns.

Table 5 Concrete Batch Strengths.

Concrete Batch No.	Slump (mm)	Load – Average (kN)	Stress – Average (MPa)	Stress – Estimated for 14 days (MPa)	Stress – Ordered (MPa)
1	55	335.886	42.766	44	50
2	115	296.604	37.765	57	65

Column Compression Tests

FRP Max Columns

Table 6 summarises the load and displacement data for all FRP reinforced columns with maximum tie spacing.

Table 6 Average FRP Max Data.

Column – Average	Max Load – Average (kN)	Max Stress – Average (MPa)	Displacement – Average (μm)
FRP Max 50	920.1	35.9	1730.2
FRP Max 65	768.0	30.0	1265.0

With an average 5MPa reduction in 14 day compressive (by cylinder test) column concrete strength came an average 6MPa drop in compressive capacity of the columns. The column testing results are consistent with the low strength results obtained from cylinder testing of the concrete ordered as 65MPa. 465μm less displacement was exhibited in columns cast from concrete batch 2 when compared to concrete batch 1. It is assumed that a smaller load would yield a smaller displacement of reinforcement. The large drop in maximum load suggests that more restraint is necessary for the GFRP bars to be most effective. Either small tie spacing or higher strength concrete must be provided to give this restraint.

FRP Min Columns

The summarised data from the FRP Min columns is displayed in Table 7.

Table 7 Average FRP Min Data.

Column – Average	Max Load – Average (kN)	Max Stress – Average (MPa)	Displacement – Average (μm)
FRP Min 50	989.0	38.6	1539.5
FRP Min 65	917.3	35.8	1656.1

The 5MPa decrease in concrete strength only yielded a 3MPa reduction in the column capacity. It can also be seen that the displacement was increased by 115μm. This goes against the thought that with higher load comes higher displacement. Whilst the average displacement has risen it is only by approximately 7%. This is not a large increase and could be due to factors relating to the proximity of failure with relation to the proximity of strain gauges.

The decrease in load capacity of the column from concrete batch 1 to concrete batch 2 was expected and in line with the reductions seen in the steel reinforced columns. This indicates that the use of smaller tie spacing has provided the restraint necessary to protect the GFRP bars from premature failure. These results could lead to maximum tie spacing requirements for compression members reinforced with GFRP bars being adopted as at approximately half that of the maximum tie spacing for steel reinforced columns.

10mm Steel Columns

The average loads and capacity of the 10mm Steel columns, along with the average reinforcement displacements are presented in Table 8.

Table 8 Average 10mm Steel Data.

Column – Average	Max Load – Average (kN)	Max Stress – Average (MPa)	Displacement – Average (μm)
10mm Steel 50	958.5	37.4	1676.0
10mm Steel 65	919.4	35.9	1553.8

For the 10mm Steel columns, a 5MPa drop in concrete strength resulted in a 1.5Mpa drop in column capacity and a 120μm reduction in reinforcement displacement. The reduction in load is as expected and solely due to the reduction in concrete strength. All 10mm Steel columns failed with rupture of tension or compression side reinforcement. This indicates that the displacements should be similar (as was the case) for both sets of columns. The locations of failure are similar between columns cast from concrete batch 1 and columns from concrete batch 2. This suggests that the reinforcement displacement should be similar. The 7% reduction in displacement may be attributable to the lower concrete strength providing less resistance to the longitudinal reinforcement. This results in a small decrease in column compressive capacity and of the reinforcement displacement.

12mm Steel Columns

The average data recorded through compression testing of the 12mm Steel columns is shown in Table 9.

Table 9 Average 12mm Steel Data.

Column – Average	Max Load – Average (kN)	Max Stress – Average (MPa)	Displacement – Average (μm)
12mm Steel 50	1101.3	43.0	1745.6
12mm Steel 65	1027.0	40.1	1395.6

The reduction in concrete strength yielded a decrease in column capacity and a decrease in reinforcement displacement, as expected. It is noted that the 12mm Steel 50 columns reached the characteristic strength of the concrete before failure occurred, whilst the 12mm Steel 65 columns slightly exceeded the characteristic strength of the concrete. This suggests that the reinforcement allowed the concrete to reach its full potential before failure occurred. This decrease in load is expected as a direct result of lower concrete strength.

The reinforcement displacement suffers a large decrease with decrease in concrete strength. This is because the 12mm Steel 65 columns failed due to concrete crushing before the stresses within the reinforcement were large enough for them to fail. This explains why the displacement of the reinforcement in these columns was not higher, because they did not fail.

Failure Modes

The main failure modes observed were rupture of compression bars, rupture of tension bars, rupture of both compression and tension bars, or failure due to concrete crushing. Table 10 presents a summary of the failure modes exhibited by the columns.

Table 10 Failure Mode Summary.

Column	Compression Side Bar Rupture	Tension Side Bar Rupture	Both Side Bar Rupture	Concrete Crushing
Concrete Batch 1	4	2	4	1
Concrete Batch 2	1	8	0	3
Total	**5**	**10**	**4**	**4**

GFRP Reinforced	4	6	1	0
Steel Reinforced	1	4	3	4

There is one column omitted from these results because the test was performed incorrectly.

FRP Min 50 (2) was the only column to have a rupture within a tie. This rupture was assessed to have been caused by the rupture of the compressive bars at the connection to the tie. The force exerted from the compressive bar failure is assessed as having caused the tie to rupture as well.

It was expected that most failures would be as a result of rupturing of the tension bars. This was the case in ten of the 23 columns. This is because the majority of the compressive loads were taken by the concrete and the reinforcing bars were only in place to combat any tension within the columns.

Compression bar rupture was expected in some cases as the bars on the compression side are bent due to the eccentricity of the load. The tensile strength of the reinforcement can be exceeded due to this, and in five cases, compression bar failure occurred. Even though the bars on the compression side of the column failed, their failure mode was in tension.

Concrete Crushing was observed in four columns, all with 12mm steel reinforcing. It occurred in the three 12mm Steel 65 columns because the compressive strength of the column exceeded the compressive strength of the concrete alone, therefore causing the concrete to crush preferentially. This was also the case with 12mm Steel 50 (2).

Overall Column Comparison

Theoretically, the GFRP column cross sections were similar in compressive capacity to the cross sections of the 12mm Steel columns. This is due to the higher tensile strength of the GFRP reinforcement. Using the Rectangular Stress Block method and assuming 40MPa concrete, a capacity of 1100kN was predicted for both GFRP reinforced columns and the 12mm reinforced steel columns. This prediction was not supported by analysis software, which predicted an ultimate load capacity of 900kN for the GFRP columns and of 1100kN for the 12mm Steel columns. It is clear that the calculations used by the software places higher emphasis on the Modulus of Elasticity than does the Rectangular Stress Block method.

Analysis software and the Rectangular Stress Block method predicted the same outcome for the 12mm Steel Columns. This was again the case with the 10mm Steel columns with both predicting failure at 1000kN. The comparison between the 10mm Steel columns and the FRP Max columns is important as it showed the effects of direct replacement (equal volumes) of steel with GFRP bars.

Testing has shown that whilst theoretically the cross sections are the same for the 12mm Steel and the GFRP reinforced columns, they do not yield the same load in practice. In addition it was found that the direct replacement of steel with the same area of GFRP does not achieve the same ultimate capacity, unless closer tie spacing is adopted.

Due to the very similar statistics shown in Table 11 concerning the FRP Min and 10mm Steel columns, a two sample, unequal variance T test was carried out using all data recorded. This test assesses the probability, with 95% confidence, of a group of data being from populations with the same mean value and can be accurately carried out as each data point is independent of the others. The null hypothesis being tested is that 'The two sample populations have an equal mean.'

Table 11 Column Statistics.

Column Type	Mean (kN)	Standard Deviation (kN)	Coefficient of Variance (%)
FRP Max	844.0375	78.48	9.30
FRP Min	953.1645	44.805	4.70
10mm Steel	938.9547	30.669	3.27
12mm Steel	1064.129	70.932	6.67

The T test is performed using complex functions of the mean and standard deviation of both sets of data. The T test indicated a 65% chance that the null hypothesis is correct. That is, there is significant support for a conclusion that very similar performance of the sample groups can be expected. This provides statistical

support for the conclusion that the FRP Min columns have very similar capacity to the 10mm Steel columns, which had the same area of longitudinal reinforcement. The similarities in capacities and displacements within the columns can be seen in Figure 2 below.

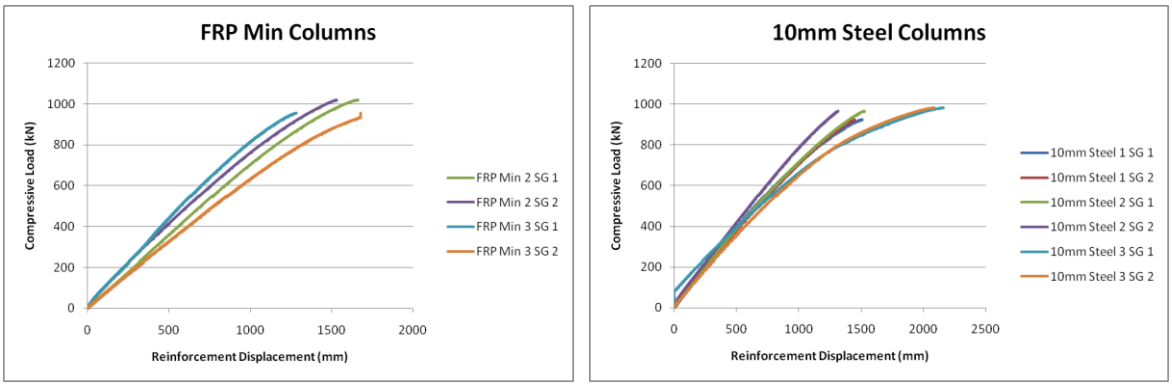

Figure 2 Load vs Reinforcement Displacement for 50MPa Columns.

Corrosion Test

The results of GFRP bars and steel bars submerged in various solutions for testing of mass loss due to corrosion can be seen in Table 12. This includes the weight before testing was undertaken, the weight after 45 days being submerged, and the total mass loss due to corrosion.

Table 12 Corrosion Test.

	GFRP Bars			Steel Bars		
Testing Solution	Weight at Day 0 (g)	Weight at Day 45 (g)	Weight Loss (g)	Weight at Day 0 (g)	Weight at Day 45 (g)	Weight Loss (g)
Distilled Water	20.5	20.5	0	109.1	109.1	0
Sea Water	22.3	22.3	0	109.8	108.9	0.9
Salt Solution 1 (10.1%)	20.9	20.9	0	161.2	160.2	1.0
Salt Solution 2 (19.8%)	21.0	21.0	0	157.2	155.9	1.3
Salt Solution 3 (32.4%)	19.9	19.9	0	109.4	107.3	2.1

As expected, no mass loss was recorded for the GFRP bars. One of the key properties that makes GFRP bars so appealing as reinforcement for concrete structures is its corrosion resistance.

There is no corrosion taking place on the steel bar in distilled water as there is no dissolved oxygen in distilled water. Rusting occurred in all four other tests for steel. In all of the salt solutions there was water and oxygen present, the two materials needed for rusting to occur. The variation of salt clearly helped to speed up the reaction as the chloride ions help to speed up the transfer of electrons from the anode to the cathode. It can be seen that with increasing levels of salt, the speed at which corrosion takes place increases. This is an expected result as there are more chloride ions free to aid in the transfer of electrons.

The sea water solution was used to simulate exposed steel near the ocean. This still exhibited a 0.9g loss for steel over a short 45 day period. Whilst this is less than 1% of the material, when these results are extrapolated over a long period of time, significant damage can be expected to the reinforcement and the structure it is reinforcing.

Whilst these results do not provide an accurate rate of corrosion or percentage loss of mass, they provide an accurate comparison between steel bars and GFRP bars when subject to salt water. Steel will corrode while GFRP bars will not.

COST COMPARISON

The material costs are summarised in Table 13. They present the costs incurred for individual materials and the cost of reinforcement for an entire column with maximum tie spacing. Prices are inclusive of GST.

Table 13 Material Cost Comparison.

Item	GFRP Cost	Steel Cost (UWA Structures Laboratory)	Steel Cost (Steel Fabricator)
Longitudinal Bars	$1.65 per m	$1.40 per m	$5.28 per m
Ties	$2.31 per tie	$1.70 per tie	$6.60 per tie
Total Reinforcement	$33.00	$25.40	$97.68

The costs for the GFRP reinforcement were obtained from an official quotation provided by a GFRP distributor in Australia. The steel costs were provided via verbal quote from the University of Western Australia Structures Laboratory. A West Australian Steel Fabricator was also invited to quote on the materials and their cost can also be seen in Table 13.

The material costs of the reinforcement for one column with maximum tie spacing is $7.60 more when using GFRP reinforcement compared to steel reinforcement. The majority of this ($6.10) was incurred from the manufacture of the ties. The increase in time for production and labour costs are, due to the small diameter, are the reasons for the high price.

It took eight hours to form the twelve GFRP reinforcement cages. This included the use of 48 longitudinal bars and 174 ties. By comparison, it took ten hours to form the twelve steel reinforcement cages, which included 48 longitudinal bars but only 120 ties. The lightweight material allowed for significantly faster construction. It is expected that this could be realised in the construction industry and has the promise of saving large amounts of time and labour due to the ease of working with GFRP reinforcement.

Even with a 30% mark-up on material cost, the 20% reduction in labour time and costs would create equivalence. This is before consideration of maintenance and design life, which is the basic compelling reason for adoption of a GFRP reinforced option.

CONCLUSIONS

The objective of this study was to further the knowledge of concrete compression members reinforced with GFRP bars. The research performed was aimed at determining the compressive capacity, reinforcement displacement and failure modes of the members. In addition, the study aimed to further the development of future construction guidelines and standards through presenting recommendations for the use of GFRP bars in compression members. The results of laboratory tests lead to the conclusion that use of GFRP reinforcement in compression members instead of traditional steel reinforcement is technically and financially viable (subject to full scale check). Although the direct replacement of steel reinforcement with GFRP reinforcement does yield a marginally lower compressive capacity, the GFRP reinforced columns are, provided that ligatures are used at 75mm centres rather than 150mm centres, of comparable capacity to steel reinforced columns with similar area of main reinforcement.

It is evident that with the direct replacement of steel with GFRP, the failure mode of the column is more explosive. This is assessed as due to the low modulus of elasticity of the GFRP bars. Tie spacing is an important design factor when using GFRP reinforcement in compressive members. Experimental work has shown that the compressive capacity significantly increased as the tie spacing decreased.

The corrosion tests performed prove that GFRP bars are not subject to the same type of corrosion displayed by steel. A compelling case could be made for their use in jetty structures where environmental conditions are harsh and the major design condition is bending and axial stress.

With the low level of research devoted to GFRP reinforcing in concrete compression members, combined with the results of this study relating to ductility of the reinforcement, failure mode of the member and warning before failure, it is suggested that somewhat higher safety factors be employed when designing GFRP reinforced members.

Cost comparison indicates that the use of GFRP bars can be quite cost effective. Whilst the GFRP materials do incur an increased start-up cost, the decrease in labour time and cost, due to the low weight material being easy to work with, is compensatory. The significant decrease in maintenance costs will make this product a valuable

material in the long term as the effects of corrosion with associated structural degradation can be confidently expected to be absent.

It is concluded from an overview of the results obtained in this experimental investigation, that the use of GFRP reinforcement in concrete compression members is a technically adequate alternative to the use of steel. Design of structures using GFRP will need to be cognisant of the need for closer ligature spacing to achieve parity with steel. The use of GFRP reinforcing bars is not isolated to but will be most beneficial in environments of high corrosion to lower the lifetime cost of the structures.

Dundas Point Boardwalk

The research performed in 2012 led to the first implementation of GFRP reinforced concrete compression members in Australia. The Dundas Point Boardwalk in Applecross was upgraded utilising GFRP bars in the concrete columns to replace the previous corroded concrete encased steel columns. It is now expected that the columns will have a serviceable life in excess of 75 years, significantly longer than the 23 year life which was achieved with the previous steel columns.

EXPERIMENTAL BEHAVIOUR OF FRP-CONFINED LARGE-SCALE CURVILINEARIZED RECTANGULAR RC COLUMNS UNDER AXIAL COMPRESSION

Junjie Zeng[1], J.G Teng[1]

[1]Department of Civil and Environmental Engineering, The Hong Kong Polytechnic University, Hong Kong

Existing research has shown that strengthening through fibre-reinforced polymer (FRP) confinement is highly effective for circular columns but much less so for square and rectangular columns due to the flat sides and sharp corners in the latter. Rounding the corners in the latter columns can enhance the effectiveness of confinement, but its benefit is limited. To overcome this problem, an alternative strengthening technique has recently been proposed by some researchers, in which the flat sides of a square/rectangular section are modified into slightly curved sides before FRP confinement (referred to as section curvilinearization). The resulting columns, referred to as curvilinearized square/rectangular columns, are much more effectively confined by an FRP jacket than the original square/rectangular columns with only corner rounding, and the associated column size increase is limited. While this section curvilinearization technique is highly attractive, there has been only very limited research on the behaviour of FRP-confined curvilinearized square/rectangular columns. In particular, all the existing experimental work has been limited to small-scale square columns (with section widths being around or below 150 mm) under axial compression.

Against the above background, a large experimental programme has been under way at The Hong Kong Polytechnic University to study the behaviour of large-scale curvilinearized RC columns under both concentric and eccentric compression. Both square and rectangular columns have been considered in the experimental programme. This paper presents a systematic experimental study on the behaviour of FRP-confined curvilinearized rectangular RC columns under axial compression to study the effects of the following parameters: rise-to-span ratio of the edge profile, sectional aspect ratio and corner radius. In addition to the presentation of experimental results, two existing stress-strain models for FRP-confined concrete in these columns are assessed to reveal their limitations.

APPLICATION OF HIGHLY-FLOWABLE STRAIN HARDENING FIBER REINFORCED CONCRETE (HF-SHFRC) IN NEW RC COLUMNS

W.- C. Liao [1,*], L.- W. Tseng [1]
[1] Department of Civil Engineering,
National Taiwan University, Taipei, Taiwan. *Email: wcliao@ntu.edu.tw

ABSTRACT

The concept of New RC, which is upgrade of concrete and reinforcement strength, was proposed in Japan in 1995. The purpose of New RC project was aimed to reduce the member sections and increase the available space of high rise buildings by using high strength concrete (f'_c > 70 MPa) and high strength rebars (f_y > 685 MPa). However, the nature of brittleness of high strength concrete may be obstacles for further application. Addition of steel fibers provides more confinement and shear capacity to enhance the ductility, particularly under high axial loading demands. Highly flowable strain hardening fiber reinforced concrete (HF-SHFRC) has good workability in the fresh state and exhibits the strain-hardening and multiple cracking characteristics of high performance fiber reinforced cementitious composites (HPFRCC) in the hardened state. This study presents the improvement of mechanical properties and confinement efficiency of high strength concrete by adding high strength steel fibers in New RC columns. Three 60×60×180cm New RC columns made of HF-SHFRC were subjected to cyclic loading to verify the enhancement of confinement and shear capacity. The test result shows that great deformation capacity is developed even stirrups spacing is increased to d/2 in New RC columns with 1.5% fiber volume fraction. The feasibility of steel fibers as a substitute for transverse reinforcement is further confirmed. Application of HF-SHFRC in New RC columns offers opportunities to significantly simplify the design and construction of columns, while ensuring adequate ductility and damage tolerance.

New RC, HF-SHFRC, HFPRCC, strain hardening, cyclic loading.

INTRODUCTION

The concept of New RC, which is upgrade of concrete and reinforcement strength, was proposed in Japan in 1995. The purpose of New RC project was aimed to reduce the member sections and increase the available space of high rise buildings by using high strength concrete (f'_c > 70 MPa) and high strength rebars (f_y > 685 MPa). However, the brittle behavior of high strength reinforced concrete during fracturing is still a primary concern despite wide application in the construction industry. Unlike normal strength concrete, as high strength concrete fractures, the fracture plane passes directly through the coarse aggregate and mortar causing an immediate drop in strength once the ultimate strength is reached and catastrophic failure. This failure behavior can be disastrous for societies like Taiwan, which is located in the Pacific Rim seismic belt. Earthquakes are frequent and unpredictable and consequently, structures must be constructed to meet minimum ductility standards.

Traditional techniques for increasing the compressive strength of reinforced concrete columns have relied on increasing the amount and number of lateral stirrups in the column. However, by increasing the amount of stirrups, constructability decreases. Resultantly, new materials are being added to traditional reinforced concrete structures in hopes of creating a reinforced concrete that has increased strength properties without associated losses in constructability. Past studies have shown that adding steel fibers to reinforced concrete increases concrete toughness and shear strength (Sugano et al, 2007). Additionally, during fracturing, the steel fibers serve a bridging role and actually provide more tensile strength during fracturing than in the solid concrete. This behavior not only inhibits the formation of fractures, it also distributes the fracture to other regions of the concrete. Only after the fibers have been completely pulled from the concrete does failure occur. Resultantly, the fibers reduce early flaking of the thin outer cover and help prevent sudden, catastrophic failure.

Highly flowable strain hardening fiber reinforced concrete (HF-SHFRC) has good workability in the fresh state and exhibits the strain-hardening and multiple cracking characteristics of high performance fiber reinforced cementitious composites (HPFRCC) in the hardened state. More information regarding HF-SHFRC can be found in the literatures (Liao et al, 2010, 2014). This study examines the behavior of high-strength reinforced concrete and HF-SHFRC columns subjected to cyclic loading, and discusses the feasibility of replacing stirrups with steel fibers. Specifically, based on cyclic loading experiments of HF-SHFRC columns, this study attempts to identify the volume fraction of steel fibers needed to reduce the number of stirrups (increase the stirrup spacing) without causing a change in the strength characteristics of the structural member. Additionally, the loading and fracture characteristics of HF-SHFRC and traditional high strength reinforced concrete are discussed.

EXPRIMENTAL PROGRAM

Materials

The cementitious materials used in this study were ASTM Type I Portland cement, ground granulated blastfurnace slag and class C fly ash. The coarse aggregate had a maximum size of 9.5 mm and consisted of solid crushed limestone from a local source, with a density of about 2.70 g/cm^3. A polycarboxylate-based superplasticizer was used in the mixture. Hooked steel fiber with circular cross-section was used, with normal tensile strength of 2300 MPa and aspect ratio of 79. The concrete compressive strengths were determined in accordance with ASTM C-39 standard compressive tests on at least six 100 x 200 mm cylinders. The concrete specified compressive strength were 70 and 100 MPa. The slump flow of HF-SHFRC used in this study is 580mm so that the workability is not the issue during construction. Four different sizes of reinforcing bars were used: D29 (6.47 cm^2) and D25 (5.07 cm^2) with yield stress of 685 MPa, and D13 (1.27 cm^2), D16 (1.99 cm^2) with yield stress of 785 MPa. The baseline tensile test for a single control reinforcing bar to determine yield strength, ultimate strength and bar strain at yield stress in accordance with ASTM E8/E8M and ASTM A370.

Specimen Design

The seismic performance of high strength steel fiber reinforced concrete is assessed by applying a double curvature, cyclic lateral loading experiment. Both a high strength reinforced concrete column and HF-SHFRC column and are tested and results contrasted. Three columns have been tested in this study. The columns had a clear height of 1800 mm with a square cross-section of 600x600 mm. There are three parameters: transverse reinforcement ratio, axial load ratio and fiber volume fraction. The label of each specimen begins with an S. The numbers following the S denote the stirrup spacing, measured in millimeters. The final numbers in the label refer to the steel fiber volume fraction, measured in %. For example the name S140-1-5 represents a specimen having a stirrup spacing of 140mm and steel fiber volume fraction of 1.5%. The specimen design is detailed in Table 1.

Table 1 Design parameters of HF-SHFRC columns

ID	Cross Section	f'$_c$ (MPa)	Longitudinal Bars SD685		Transverse Bars SD785			$\frac{P}{A_g f_c'}$
			$n - d_{bl}$	ρ_l (%)	d_{bt}	Spacing (mm)	ρ_t (%)	
S140-1.5		70 (V_f=1.5%)	16-D25	2.25	D13	140	0.76	0.57
S260-1.5		70 (V_f=1.5%)	8-D29 8-D25	2.56	D16	260	0.64	0.42

S130-1.0		100 (V_f=1%)	8-D29 8-D25	2.56	D16	130	1.28	0.42

Test Setup

The experimental investigation involved data recording from gauge instrument. From gauges instrument will result force-displacement plot, strain data for longitudinal and transverse reinforcement, data of shear strain and curvature. The test of the specimens performed in National Center for Research on Earthquake Engineering (NCREE) using Multi-Axial Resting System (MATS) that built in 2007. The MATS conducted double-curvature cyclic deformation. The maximum axial and lateral load that can be applied by MATS is 60 MN and 7MN, respectively. The lateral force was set from the hydraulic actuator that placed in the bottom as shown in Figure 1(a). The horizontal actuator was controlled by a prescribed horizontal displacement history. For all the specimens, the axial load maintained constant. The given loading for all specimens and the displacement history was applied with three cycles for each level as shown in Figure 1 (b). For each cycle of each loading phase, once maximum displacement was obtained, loading was temporarily stopped and the fracture patterns were marked and recorded through photographs. The experiment was continued until a significant loss in axial bearing capacity of the column member was observed. Significant loss in axial bearing capacity was interpreted using the following guidelines: rapid reduction in axial bearing capacity; or sudden MATS loading plate displacement greater than or equal to 20 mm. It is worth mentioning that a qualified column should satisfy the seismic criteria, which is the drift capacity at 80% of maximum lateral load should not less than 3% drift.

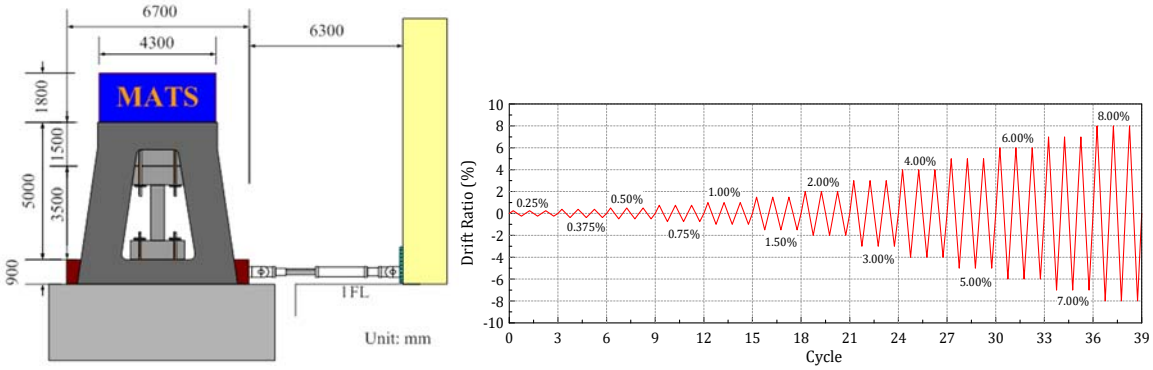

Figure 1 (a) Test setup with MATS; (b) loading protocol

Experiments in this study were conducted under high axial forces, resultantly the P-Δ effect was obvious, and consequently, correction was required. Correction methodology is detailed in Figure 2. Once both the friction between the specimen and the lifting table and the P-Δ effect have been corrected, a complete hysteresis loop for the column specimen can be obtained.

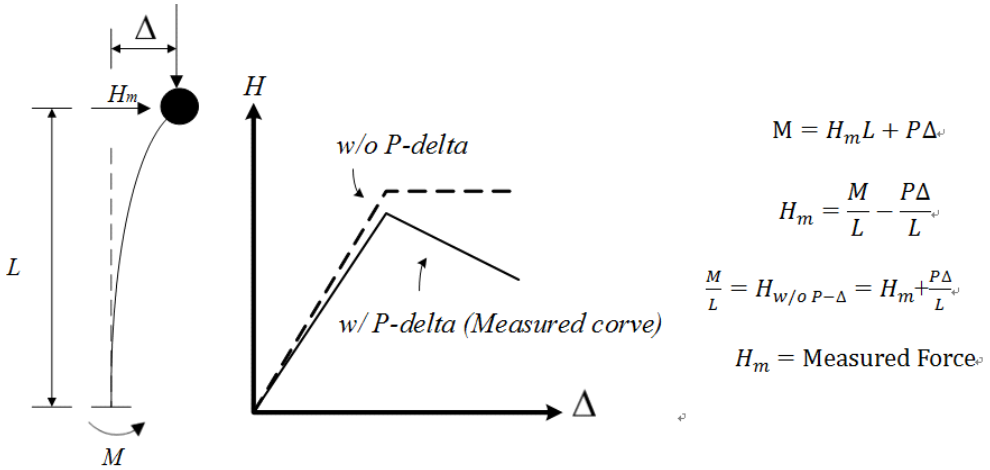

Figure 2 Methodology of P-Δ effect correction

TEST RESULTS

S140-1.5

The S140-1.5 specimen is compared to specimen B5 reported in Chang (2010). Both specimens have the same cross-section design, including longitudinal and transverse reinforcement layout. Stirrup and cross-ties have hooked ends bent at 90°and 135° respectively. They were tested under high axial loading ratio of 0.57. The hysteresis loops for both specimens are plotted in Figure 3. The ultimate drift (drift corresponding to 80% maximum lateral capacity) for S140-1.5 was a drift ratio of 3.23%, which is greater than 3% of the standard. For specimen B5, before lateral strength reached 80% of the ultimate, all capacity to bear axial loads was lost. The drift ratio corresponding to failure was 1.25%, a level far from the requirements to meet standards.

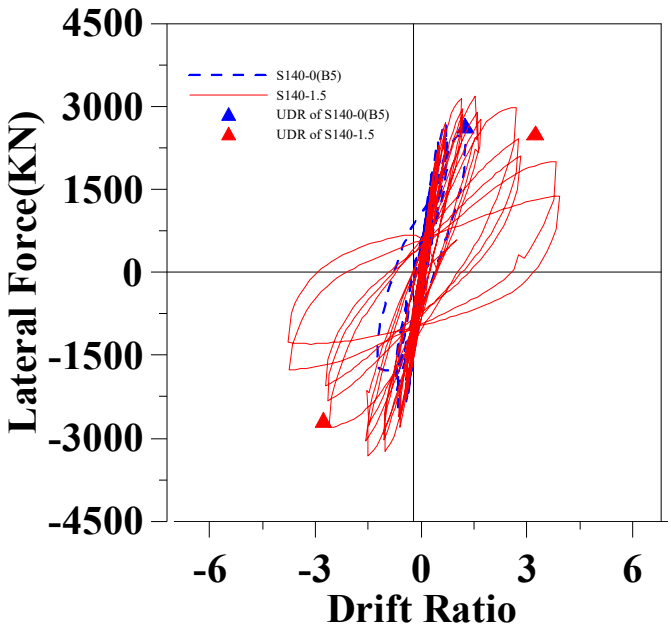

Figure 3 The hysteresis loops for S140-1.5 and B5 (Chang, 2010)

The ultimate strength of specimen S140-1.5 was 11% (314kN) higher than that of specimen B5. Additionally, specimen S140-1.5 exhibited a full hysteresis loop. Before the loading platform reached a displacement of 0.75%, both specimens remained elastic, and the lateral stiffness remained constant. Moreover, during the 2nd and 3rd hysteresis loops, the reductions in the lateral force were not obvious. At a platform displacement of 1%, the S140-1.5 specimen still remained in the elastic zone, however, the lateral strength of specimen B5 dropped, demonstrating that specimen B5 entered into the plastic zone before the S140-1.5 specimen and that the ultimate strength of the B5 specimen was reached. At a platform displacement of 1.5%, the lateral stiffness of specimen S140-1.5 began to drop, but lateral strength continued to increase. Under the same conditions, the lateral strength of specimen B5 was already lower than the ultimate strength. Before a second hysteresis loop could be applied, B5 had failed. Once a loading platform 2% was reached, specimen S140-1.5 finally reached ultimate strength, but continued to develop strength up to a platform displacement of 4%. Before a 3rd hysteresis loop could be applied, specimen S140-1.5 also failed.

Experiment results of specimen S140-1.5 and B5 demonstrate that if the confining strength of a concrete column is inadequate, which may be the case for columns that have been constructed using wide stirrup spacing and thin cross ties, adding steel fibers to the concrete can increase the performance of the concrete and meet structural standards.

S260-1.5

The design cross section and longitudinal reinforcement ratio of S260-1.5 is the same as the T100-1(Huang, 2013). The axial load ratio applied to both specimens was 0.42. The main difference is that the transverse reinforcement of T100-1 was designed in accordance with ACI 318-14 (2014), which requires notable reinforcement amount for high strength concrete or columns under axial loading ratio higher than 0.3. By

contrast, in S260-1.5, the spacing between stirrups is the maximum value specified by ACI 318-14 for shear resisting reinforcement, half of the effective depth (d/2). The transverse reinforcement ratio of S260-1.5 and T100-1 was 0.64% and 1.67%, respectively. The hysteresis loops for both specimens are plotted in Figure 4.

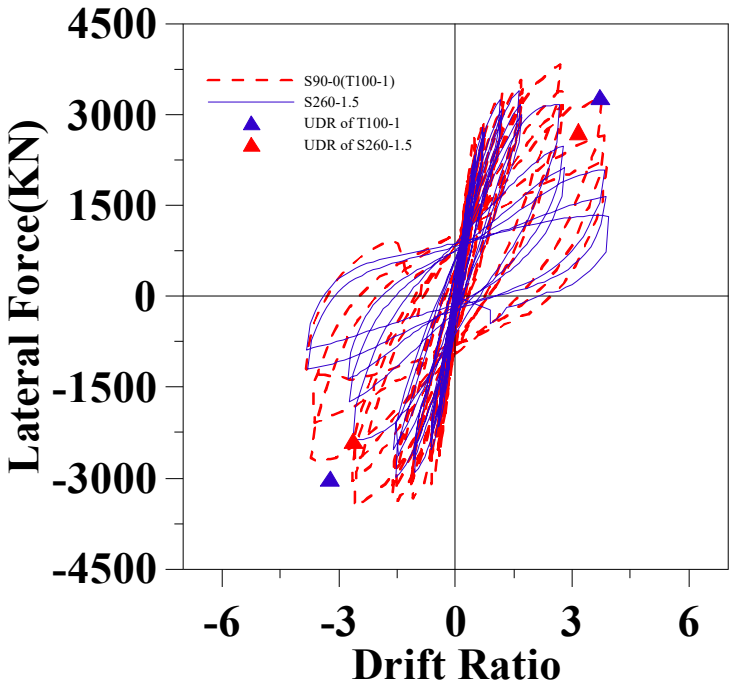

Figure 4 The hysteresis loops for S260-1.5 and T100-1 (Huang, 2013)

The ultimate drift for S260-1.5 was 3.16%. Under these conditions, the lateral strength of the specimen was 2,715kN. In contrast, the ultimate drift for T100-1 was 3.72%. The lateral strength of the specimen under these conditions was 3,290 kN. For both specimens, once the positive ultimate strength was reduced to 80% of ultimate, the drift ratio was greater than the 3% standard. During initial loading, the behavior of specimens S260-1.5 and T100-1 were very similar; the stiffness of both specimens rapidly deteriorated once the loading platform reached a displacement of 1%. Up to a loading platform displacement of 2%, the hysteresis loops of both specimens were nearly the same and plot on top of each other in Figure 4. However, specimen S260-1.5 reached ultimate strength during this loading period and once the loading platform displacement reached 3%, the lateral strength of specimen S260-1.5 clearly decreased. Additionally, during the 2nd and 3rd hysteresis loop, the lateral strength and stiffness rapidly dropped. In contrast, under the same loading cycle, the lateral strength of the T100-1 sample continued to rise until the ultimate strength was reached. Once the displacement of the loading platform reached 4%, the lateral strength of each specimen differed by 50%.

This experiment tested the contribution to strength by the steel fibers even at the maximum stirrup spacing (d/2). Results show that the steel fiber reinforced specimens meets ultimate strength standards of a drift ratio of 3% at a reduction of 20% ultimate lateral capacity.

S130-1.0

The design cross section and longitudinal reinforcement ratio of S130-1.0 is the same as the T100-1 (Huang, 2013). The axial load ratio applied to both specimens was 0.42. The stirrup spacing of S130-1.0 is 1/4 of the effective depth (d/4). The hysteresis loops for both samples are shown plotted together in Figure 5. The ultimate drift ratio for S130-1.0 was 3.78% and that for T100-1 was 3.72%. For both specimens, once the ultimate strength was reduced to 80% ultimate, the drift ratio was greater than the 3% standard.

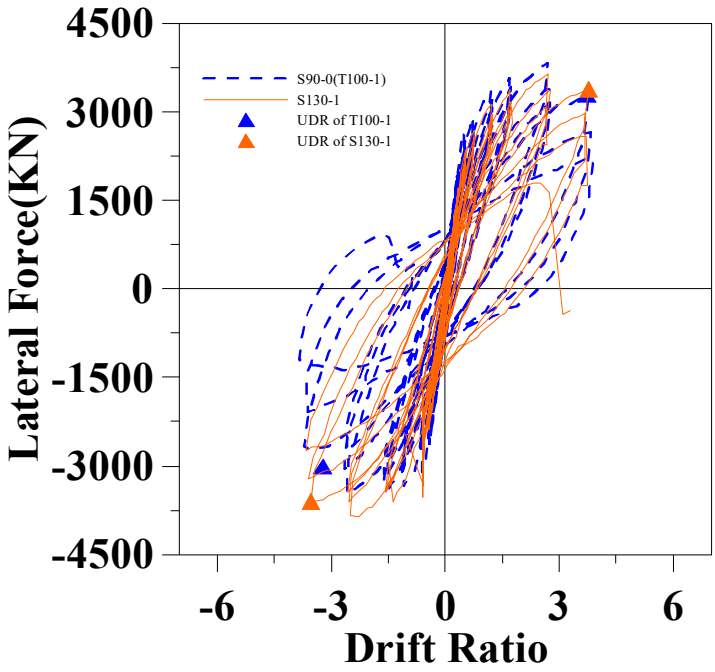

Figure 5 The hysteresis loops for S130-1.0 and T100-1 (Huang, 2013)

In the first half of the loop, both samples behave the same; however the stiffness and lateral strength of the T100-1 specimen is higher. At a loading platform displacement of 1%, the stiffness of both specimens began to rapidly decrease. Once a loading platform displacement of 3% was reached, the ultimate strength of the specimens was reached. Notably, at a loading platform displacement of 4%, the lateral strength of the specimens rapidly decreased, however the rate at which specimen T100-1decreased was far greater than the rate associated with specimen S130-1.0 and it was at this point in the hysteresis loop that the lateral strength of the T100-1 specimen was less than S130-1. Once the 2nd and 3rd hysteresis loops commenced, the difference in lateral strength and stiffness of the two samples only increased. In this comparison, the confining strength developed by the steel fibers in the steel fiber reinforced concrete remained relatively constant during repeated lateral loading. Once a loading platform displacement of 4% was reached during the 3rd hysteresis loop, both specimens failed under axial loading.

Based on the results of loading tests performed on specimens S130-1, S260-1.5 and T100-1, to a certain degree, it has been demonstrated that lateral stirrups can be replaced by steel fiber. As the stirrup spacing is increased, steel fibers in the concrete increasingly contribute to the strength of the concrete, but there is a limit to this strength contribution. A the maximum specified stirrup spacing (d/2) and a steel fiber volume fraction of 1.5%, the specimen met strength standards, however, in later loading stages, the strength of the specimen drastically decreased, demonstrating that for later stages in the loading cycle, stirrups are needed to ensure a stable confining strength and also that a specified maximum spacing of d/2 is reasonable requirement. This finding is worth contemplating and shows that to ensure strength performance during strain, a minimum number of stirrups are needed and the steel fibers are not able to completely replace the stirrups. However, the steel fibers can reduce stirrup spacing and the number of complicated ties and improve the constructability of reinforced concrete.

CONCLUSIONS

This study performed double loop, cyclical lateral loading tests on high strength, steel fiber reinforced concrete columns to examine the difference in high strength concrete and the effect of steel fibers on stirrup spacing. Additionally, the performance and stiffness reduction of the steel fiber reinforced concrete columns were examined. Based on experimental observations and a literature review, the following conclusions were reached:

(1) The performance of columns was enhanced by adding steel fibers to the concrete. In situations where confining strength from the stirrups is inadequate, the contribution by the steel fibers to toughness is most apparent.

(2) The ultimate strength of specimen S140-1.5 was reached once the longitudinal reinforcement yielded, demonstrating that flexural strength was fully developed and that a significant shear capacity provided by fibers maintained. Once the lateral strength was reduced to 80%, the drift ratio standard of 3% was still met.
(3) Steel fibers can be used to substitute some stirrups but not all. A comparison of specimens S130-1.0 and T100-1 was performed. Despite the stirrup spacing of specimen S130-1 being 44% (40mm) greater than specimen S90-1, the loading behavior of the two specimens was nearly identical.
(4) The stirrup spacing used on specimen S260-1.5 is the maximum spacing specified (d/2) and the criterion of an ultimate drift ratio of 3% was fulfilled. However, during later loading stages tough, the stirrups provided most of the confining strength, demonstrating that even with the addition of steel fibers, stirrup specifications must still be followed.
(5) The addition of steel fibers to concrete limits the reductions in lateral stiffness during loading. When confining strength provided by the stirrups is inadequate, such as specimen S130-1.0, a constant stiffness is maintained by the steel fibers. In some situations, S130-1.0 outperformed specimens built using a smaller stirrup spacing. However, for large stirrup spacing, such as specimen S260-1.5, even after the addition of steel fibers, the lateral strength of the specimen during advanced loading stages is greatly reduced.
(6) The feasibility of steel fibers as a substitute for transverse reinforcement is further confirmed. Application of HF-SHFRC in New RC columns offers opportunities to significantly simplify the design and construction of columns, while ensuring adequate ductility and damage tolerance.

ABSTRACT

The use of conventional building materials is facing two main challenges of excessive cost and large-scale depletion of the sources thus creating environmental problems. These challenges demand that alternative building materials be explored that are not only affordable but are also environmentally friendly. In this regard and inspired by the global need for sustainable development, earth(soil) is re-emerging as the grand eco-material for building construction due to its availability, environmental/cultural appropriateness, structural adequacy, familiarity to the local people, "breathability", health benefits, amongst others. This paper presents results of experimental work in Kenya aimed at utilizing earth in formal housing constructions with a view to alleviating the severe housing shortage in the country. Studies were conducted on structural performance of various types and blends of earth material, from which a suitable blend was selected and used to construct a model two-storey rammed earth building. The model house had load-bearing walls of rammed earth, and a hollow-pot reinforced concrete slab containing light-weight stabilized soil blocks. The rammed earth two-storey model house was tested for vertical load resistance using sacks of sand. Results obtained from this study indicate that certain blends of local earth materials had higher stabilized block strengths than the standard dressed stones which are normally used in construction in Kenya. Further, the model eco-house was able to resist applied vertical loading with minimal deflections within the standard requirements. The model house has been in use as an office building for over four years with negligible deterioration in terms of material erosion or cracking or deflections.

INTRODUCTION

About nine (9) million Kenyans are in need of proper housing, with the capital city of Nairobi with a population of three million having about 60% of its residents leaving in slums [1]. Accordingly, the provision of shelter is a key item on the national agenda, and solutions are currently being sought not only in reducing the cost of construction but also ensuring environmental preservation and enhancement of the social fabric in line with global trends towards sustainable development. Thus, the focus and mission of ongoing research and development activities is geared towards complementing government efforts in shelter provision by availing sustainable eco-materials and eco-technology for all, viz, materials/technologies that are environmentally friendly, locally based, culturally acceptable, affordable, structurally sound and durable. Earth-based materials are proving to be the grand eco-materials of this century (Venkatarama et al. 2010; Graham et al. 2001; Martins et al. 2015; Oyawa 2004).

The work herein presents results of studies on structural performance of various types of earth-based wall panels, culminating in the construction of full scale prototype two-storey house from rammed earth. **Rammed earth** construction is an ancient technique that is under revival as mankind seeks sustainable building materials and natural building methods (Voral *et al.* 2014; Windstorm *et al.* 2013). The technique emphasizes on use of local natural raw

materials such as earth, cowdung, lime or gravel to build walls or structures. The objectives of this study were to determine appropriate material mix ratios for the construction of stable earth-based structural element, evaluate the impact of compaction methods on strength of earth-based structural element, determine the structural performance of wall panels made of varying types of blocks and jointing mortar, and to evaluate the stability and durability of model eco-structures made of earth-based material.

EXPERIMENTAL WORK

Experimental work involved material property tests on constituent materials e.g. soils, river sand, and quarry dust, employing standard test methods stipulated in Kenya/British codes. Further tests were on various types of compressed earth blocks (CEB), testing of wall panels of various sizes and of different materials, and finally constructing and testing a full scale 2-storey rammed earth house. Hence, tests undertaken may be classified as standard material property tests, compressed earth block (CEB) tests, wall panel tests, and stability/durability tests on full-scale prototype rammed earth structures.

Compressed earth block (CEB) tests were conducted to determine suitable mix ratios for the construction of model eco-structure. Standard compressed earth blocks (CEB) of size 290x140x120mm high were prepared by mixing soil or stabilized soil at optimum moisture content, and then compressing by a standard press block machine (Fig. 1). The main variables in these tests included the type of soil (Murram-MS or red clay soil-RCS or black cotton soil-BCS), the extent of stabilization by cement or lime or quarry dust, and the mode of compaction. The aim of tests on compaction method was to compare the strength of blocks produced using only the standard press block machine (designated CM blocks) and those produced by using hand compaction on 2 layers with the final flat topping being achieved using the press block (designated HC+CM) as listed in Table 1.

(a) CEB preparation using press block

(b) testing of CEB in compression

Figure 1 Block making and block testing

Table 1 Mix ratios to investigate the effect of hand compaction on eco-block strength

Mix series	Mix designation	Description
Black Cotton Soil (BCS) series	BCS-63S-6C	BCS with 63% sand and 6% cement
	BCS-63S-4L-2C	BCS with 63% sand, 4% cement of lime and 2% cement
	BC-4L-2C	BCS with 4% cement of lime and 2% cement
Red Coffee Soil (RCS) series	RCS-63S-6C	RCS with 63% sand and 6% cement
	RCS-63S-4L-2C	RCS with 63% sand, 4% cement of lime and 2% cement
	RCS-4L-2C	RCS with 4% cement of lime and 2% cement
Murram Soil (MS) series	MS-20S-6C	MS with 20% sand and 6% cement
	MS-20S-4L-2C	MS with 20% sand, 4% cement of lime and 2% cement
	MS-4L-2C	MS with 4% cement of lime and 2% cement

The compressed earth block specimens were covered and left to cure until the time of testing. Compressive test on CEB was conducted by placing each block between the platens of a Universal Testing Machine, and gradually compressing until failure while recording the failure strength. Each test result was an average of at least three block specimens.

Wall panels tests involved preparing walls of size 1200mm length by 700mm high by 140mm thick on a thick steel plate, lifting the arrangement onto a testing frame and testing under compressive load regime while monitoring loads, displacements and strains. The wall panel tests were conducted to determine the effect of jointing mortar on CEB wall panel strength, and also to compare the behavior of CEB wall panels vis-à-vis stone wall panels. The variables were the type of block material for the wall, and the type of jointing mortar i.e. conventional mortar of sand and cement in a ratio of 1:4 (Wall CS1:4), conventional mortar of sand and cement ratio 1:16 (Wall CS1:16) having similar strength to the stabilized blocks, and eco-mortar of the same materials as block i.e. cement, quarry dust, quarry chips and murram in a ratio of 1:4:4:8 (Block mix BM 1:4:4:8). Table 2 gives typical details of the walls tested with the aim of evaluating the effect of jointing mortar, where the compressive strength test for mortar was done on 100x100x100mm cubes using universal testing machine at the age of 7 days. Mortar strength results reveal that replacing river sand with a blend of quarry dust, quarry chips and murram has positive effect on strength i.e. the strength of BM 1:4:4:8 mortar is higher than the strength of CS1:16 mortar.

To determine the effect of block type on wall strength, wall panels made of stabilized soil blocks, unstabilized soil blocks and standard dressed stone blocks, were prepared on the testing frame, cured and tested under compressive load regime (Figs. 2 and 3). For all the wall panels, the proportion of mortar mix was 1:3 (cement:sand). The CEB wall panels had a dimension of 1000 x 520 x 140 mm while the conventional stone wall panels had a dimension of 1000 x 520 x 150mm.

Table 2(a) Material properties (Compressive strength of eco-block and mortar types)

Specimen designation	Description	Percentage of cement in mix (%)	Avg. Compressive strength (MPa)	
Eco-Block (MurQDndarQDnbi 6% cem)	Eco-block of mix ratio 1:4:4:8 of cement: quarry chips: quarry dust: murram	5.9	4.1		Jointing mortar			
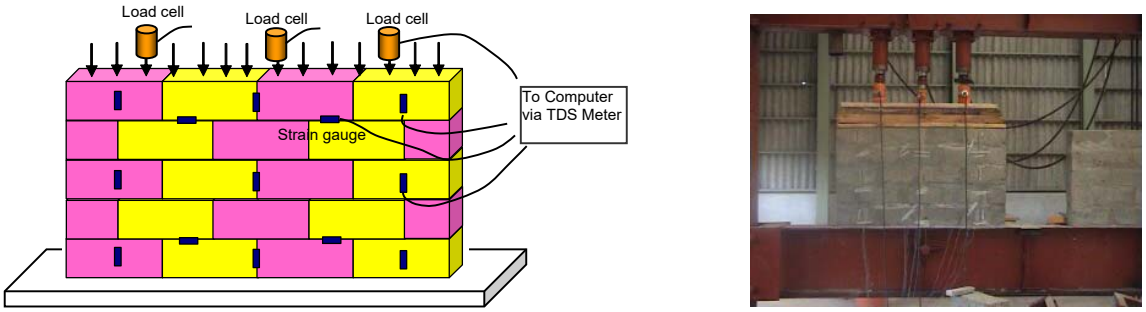
Jointing mortar CS1:4	Mix ratio of 1:4 of cement: sand mortar	20.0	4.3	
Jointing mortar CS1:16	Mix ratio of 1:16 of cement: sand mortar	5.9	0.7	
Jointing mortar Block mix BM 1:4:8:8	Mix ratio of 1:4:4:8 of cement: quarry dust: quarry chips: murram mortar	5.9	1.1	

Table 2(b) Description of wall panels (Effect of mortar series)

Wall specimen designation	Description of jointing mortar used for wall
Wall CS1:4	Mix ratio of 1:4 of cement: sand mortar
Wall CS1:16	Mix ratio of 1:16 of cement: sand mortar
Wall BM 1:4:8:8	Mix ratio of 1:4:4:8 of cement: quarry chips: quarry dust: murram mortar

During compressive test on each wall panel, timber planks were placed on the top of the wall followed by load cells to measure the load applied. Timber planks were used to distribute the load over the wall. The electric resistance strain gauges were pasted at several locations of wall vertically and horizontally; some on the blocks while others on

mortar. The load cells and the strain gauges were connected to TDS 302 strain meter, which was connected to a computer. The load was applied through hydraulic jacks, mounted at several locations on top of the wall. The experimental set up is as shown in Fig. 3.



(a) Schematic representation (b) Photo

Figure 3 Experimental set up for tests on wall panels

Tests on full-scale prototype rammed earth eco-structures were geared towards assessing the stability and durability of the prototype single storey and 2-storey rammed earth buildings. The constructed two-storey structure was subjected to 1.6 time the anticipated live loads by placing sand bags on the slab and measuring deflections. The rammed earth building was further subjected to prevailing weather conditions over several years so as to assess the impacts of weather. Further, a rammed earth single storey building made stabilized with materials **other than** standard Portland cement has been constructed as is undergoing evaluation under the effects of prevailing weather conditions.

RESULTS AND DISCUSSION

Material Properties

Table 3 gives basic material properties that include **bulk densities, water absorption, fineness modulus and silt content**. It is observed that river sand has the highest bulk densities while quarry dust from dressed stone plant (QDNbi) has the lowest bulk density, which is even lower than that of murram soil. The values obtained compare well with the results reported by Ilangovan *et al.* (2008) and Mulu *et al.* (1998). Murram has the highest silt content, highest water absorption and highest fineness modulus, and hence a good "candidate" for blending with other coarser materials. BS 882:1973 specifies maximum silt content of 15% in crushed stone sand and 3% in natural or crushed gravel sand, hence murram soil which has a silt content of 14% does not meet the minimum requirements for silt content according to British standard BS 882:1973. One of the roles of laterite in this study was to modify the quarry dust material to be used for masonry block manufacture.

Table 3 Basic material properties

PHYSICAL PROPERTIES		RIVER SAND	QDNbi	QDNdar	MURRAM
Specific density		2.6	2.63		
Bulk density	Loose condition	1405	1354	950	1162
(kg/m^3)	Dense condition	1547	1496	1050	1294
Water absorption in %		1.3	2.0	6.5	6.8
Silt content %		2.7	5.5	12.5	14.0
Fineness modulus		2.27	4.46	1.78	5.46

Shrinkage of various soil mixes was also determined by preparing saturated mixes in boxes of size 40x40x600mm, and leaving the mixes to dry out. Shrinkage measurement and crack observation was done after 3 days. Table 4 shows respectively the type of mixture, the number of cracks, amount of shrinkage, and shrinkage patterns. The table reveals that black cotton soil and red coffee soil have the highest shrinkage and number of cracks, while murram soil did not present any crack. It was also observed that as sand and quarry dust are added to the soil mix, the amount of shrinkage reduced considerably.

Table 4 Linear shrinkage and cracking of soil mixes

Blocks label	Number of cracks of large width	Linear shrinkage Ls (mm)	Shrinkage pattern
RCS (Red coffee soil)	5	30	
RCS-20QD (RCS blended with quarry dust)	1	13	
BCS (Black cotton soil)	3	33	
BCS-20QD (BCS blended with quarry dust)	1	26	
MS (Murram soil)	0	12	
MS-20S (Murrum blended with sand)	0	8	

Effect of Material Type and Mix Ratio on CEB Strength

The effects of material type and mix ratios on strength of CEB are given in Figs. 4 and 5. Results obtained for CEB are compared to conventional building stones that are used to construct load bearing walls in Kenya as presented in Fig 4. A glance at Fig. 4 confirms that novel eco-blocks consisting of a blend of murram (Murr) and other materials such as quarry dust from building stone dressing plant (QDndar), pumice dust from volcanic eruption (Pum) and quarry dust obtained from aggregate crushing plant (QDnbi) have comparable or higher strengths than the minimum strength required for stabilized blocks of 2.5 N/mm^2, and further still, these eco-blocks have comparable or higher strengths than conventional dressed stone blocks used in Kenya. Eco-block, which is stabilized by 10% cement and made from a blend of murram and pumice dust i.e. MurrPum, has the highest strength, which is higher than the strongest stone block, thus affirming the great potential of eco-blocks as alternative environmentally friendly materials for construction in the 21st century.

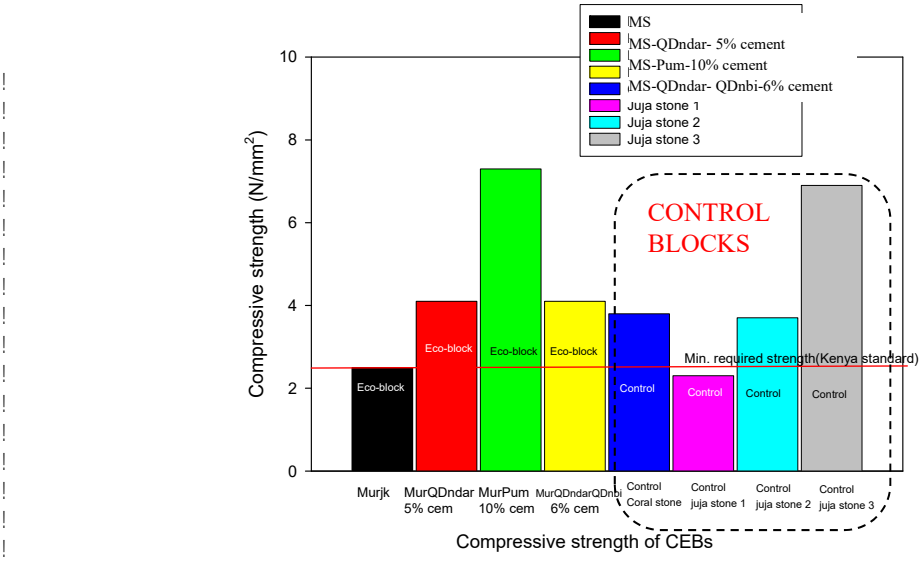


Figure 4 Comparison of CEB with conventional dressed building stones

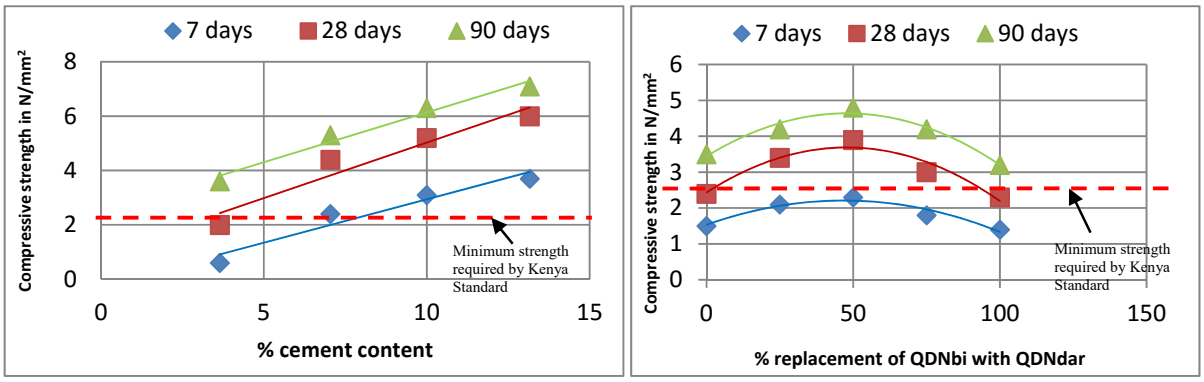
!

The study also sought to determine the variation of compressive strength of CEB with increasing cement content, and the effect of replacement of QDnbi with QDNdar on CEB strength. Constituent materials for the CEB were cement, murram soil, quarry dust from stone dressing quarries (QDNdar) and Quarry dust from aggregate crushing plant (QDNbi). The amount of quarry dust from dressed building stone quarry (QDNdar) was varied as a replacement of the content of quarry dust from aggregate crushing plant (QDNbi). Results obtained are shown in Fig. 5 where it is clearly observed that CEB strength increases linearly with increased cement content and with age of curing. It also observed that an optimum of 50% replacement of QDNbi by QDNdar is desirable. Generally, masonry blocks containing a blend of alternative materials Murr, QDNbi and QDNdar have better performance in terms of strength and water absorption.

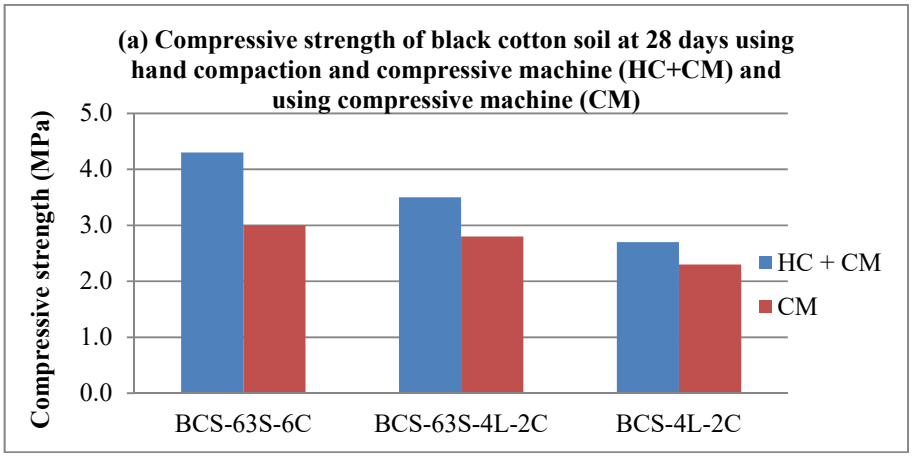


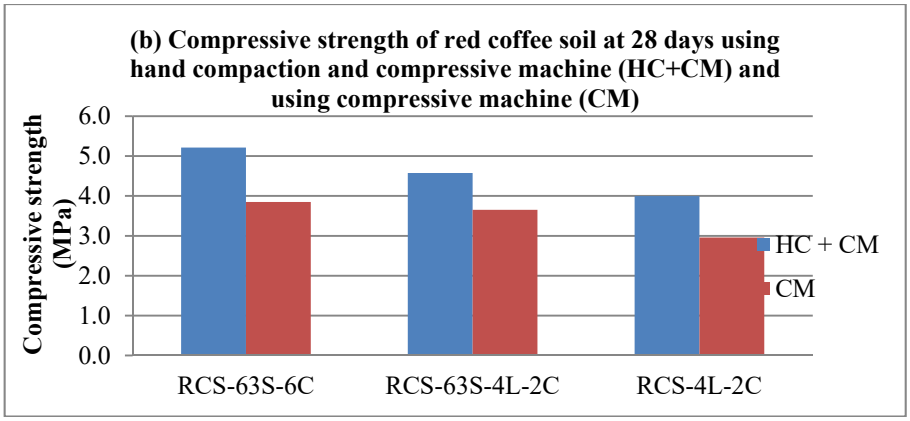
(a) Effect of cement content (b) Effect of QDndar as a replacement of QDnbi

Figure 5 Variation of compressive strength of CEB with cement content, and QDndar content

Effect of Hand Compaction on Compressive Strength of Eco-blocks

As presented in Fig. 6, hand compaction (HC+CM) produced blocks of increased compressive strength as compared to machine compaction (CM). The maximum impact is for mixes with 6% cement where for black cotton soil serie, the compressive strength of blocks increased from 3.01 MPa for machine compaction to 4.3Mpa for hand compaction, for red coffee soil series strength of blocks increased from 3.9 MPa for machine compaction to 5.2 MPa for hand compaction, and for murram soil series the compressive strength of blocks increased from 4.4 MPa to 6.2 Mpa for murram soil. The results confirm what Fetra *et al.* (2011) determined i.e. the density of the compressed earth block is consistently related to its compressive strength and compactive force applied during production.





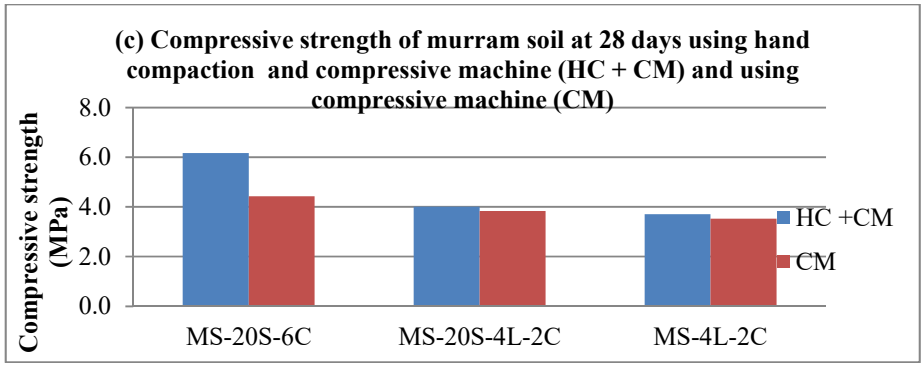


Figure 6 Effect of hand compaction on compressive strength of different types of block at 28 days

Effect of jointing mortar on strength and strain distribution of wall panels

Fig. 7 clearly demonstrates that wall BM 1:4:4:8 jointed in weak mortar similar to the block mix gives the highest ultimate load compared to the other wall panels. In fact, wall CS 1:4 jointed with the strongest cement-sand mortar has the lowest ultimate load. This indeed is an important result as it goes against expectations. It would seem that the homogeneity of the wall panel is of utmost importance with regard to strength and structural performance of walls. Thus, a wall panel made of blocks and jointing mortar that are similar in strength and characteristics has much better performance than a wall made of jointing mortar whose strength is much higher than the blocks. From economic point of view, it would seem prudent to use jointing mortar of similar strength and characteristics as the block. Accordingly, the higher the block strength, the higher the mortar strength required and vice versa.

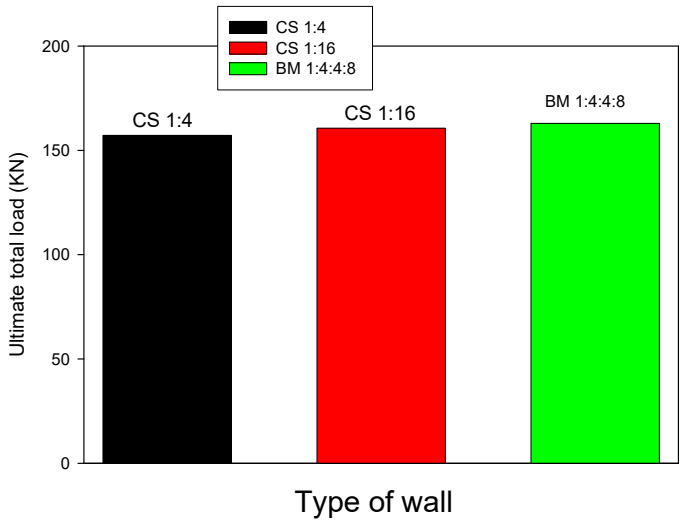

Fig. 11 Ultimate load for wall types

Figure 7 Ultimate load for wall types

Effect of Block Type on Wall Panel Flexibility and Strength

Figures8 represents the maximum stress supported by each wall before failure. It is determined that the stress in the wall types are 1.0411N/mm^2, 1.0643N/mm^2 and 0.9517 N/mm^2 respectively for wall made of unstabilized soil block, wall made of stabilized soil block, and wall made of stone block respectively. This result shows that the compressive strength of stabilized compressed earth blocks is higher than the compressive strength of stone blocks wall used in this works. Moreover, Fig. 8 reveals that strength of the wall is lower than the compressive strength of the unit blocks used for masonry. From these observations it may be inferred that the compressive strength of a blocks unit is not a direct measurement of the compressive strength of the masonry. This was confirmed by Hendry *et al.* (2004) who determined that the compressive strength of masonry varies roughly as the square root of the nominal unit crushing strength and as the third or fourth root of the mortar cube strength.

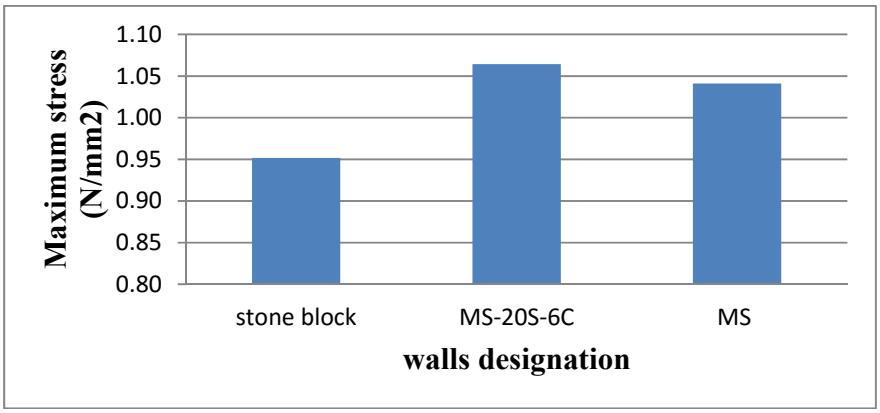

Figure 8 Maximum stress in the walls

The structural adequacy of masonry walls depends upon a number of factors such as quality of masonry units and mortars, methods of bonding, unsupported height of walls hence the strength of masonry is affected by the strength of the blocks, the water/cement ratio and the bond between the masonry unit and the motar. The respective strength of blocks was 2.9 MPa, 4.4MPa and 2.1 MPa respectively for unstabilised soil block, stabilised block and the conventional stone block from Ndarugu quarry. According to Gichuhi (2011), Quarry stone has a compressive strength of between 2 to 5 N/mm2 depending on the type of stone which varies from region to region. It was noted that the strength of conventional stone block used in this work is less than the 2.5 MPa strength of stabilised block required by the KS-02-107:1993. Mortar has a function to bond the bricks or blocks together so that they will resist the loads applied to the wall by giving strength and durability.

Stability and Durability of Full-scale Prototype Single and Two-storey Rammed Earth Buildings

Further to experimental work on structural components of a building structure, actual construction of model eco-structures was undertaken by constructing single and two storey buildings of load-bearing rammed earth wall (Figs 10 and 11). The construction of model full-scale structures was based on test results from material property tests, CEB tests and wall panel tests as illustrated in Figure 9.

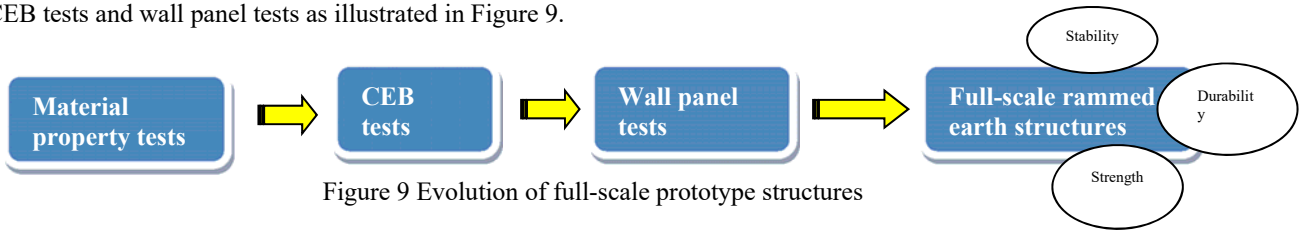

Figure 9 Evolution of full-scale prototype structures

Prior to normal use as a structure, the two-storey model eco-structure with load bearing rammed earth wall was subjected load testing by applying to 1.6 times the anticipated live loads by use of sand bags (see Fig. 11b). Floor displacements were measured using a survey staff. Results observed demonstrate that the two-storey structure was

able to resist applied loading without any visible damage, and the measured floor displacements were minimal and within acceptable levels.
After load testing, the constructed prototype eco-structures have been subjected to prevailing weather conditions and normal use load. To-date these structures have performed satisfactorily both under the weather and normal use loading. Work by Bui et al. (2009) on the durability of different types of stabilised and unstabilised rammed earth walls involved constructing and exposing rammed earth walls for 20 years to natural weathering in a wet continental climate. Results obtained in this study confirm the structural adequacy and stability of rammed earth walls since it was observed that none of the walls had shown complete collapse.

Generally, earth-based construction is seen to be the grand eco-material of this century owing to low embodied energy, low carbon dioxide emissions, very low pollution impacts, and good thermal comfort, amongst other reasons (Pacheco-Torgal et al. 2012). However, the use of ordinary Portland cement for soil stabilization increases embodied energy, and hence further studies are required to evaluate alternative stabilizers that are eco-friendly such as lime, gypsum, and industrial waste products.

Figure 11 Construction and testing of a model two-storey building from rammed earth

CONCLUSIONS

The work presented herein demonstrates that eco-blocks made of stabilized murram soil and quarry dust have comparable or higher strength than conventional dressed stone blocks used in Kenya. It is further determined that the use of jointing mortar of similar characteristics to the block produces wall panels of higher strength and

structural characteristics than blocks jointed in higher strength mortar. This is attributable to homogeneity of the wall panel made of similar jointing mortar. This is therefore a potential saving in masonry construction because, the cement content in the mortar is only 5.9% as compared to the conventional mortar with cement content of 20%.

Results of the study also vividly demonstrate the viability of constructing eco-buildings in Kenya employing local sustainable construction materials. Constructed full-scale prototype single storey building and two-storey building of rammed earth load-bearing wall were found to perform satisfactorily under applied loads and prevailing weather conditions.

Abstract:

Optimizing concrete mixtures with regard to replace a part of cement content with supplementary cementitious materials can prompt the design of ecological-self consolidating concrete. By replacing more than 60% of cement with residual product from other industries such as Fly Ash, Micro Silica, and lime, the energy consumption and CO2 emission of concrete are reduced. This study was performed to monitor the creep and shrinkage of high volume supplementary cementitious material of self consolidating concrete (HVSCM-SCC) and ensure desired performance of concrete. Total sixteen and Twenty Four specimens from different concrete mixtures with different replacement level (up to 75% of cement replacement) were monitored for creep and shrinkage respectively. Moist and accelerated curing regimes were utilized in this study to see the effect of accelerated curing on creep and shrinkage of HVSCM-SCC. Mechanical properties of different age 1,3,7,28,56 and 90 days were conducted. Experiments have shown that 75% level replacement of cement experienced low creep and shrinkage rate than other mixtures. The creep and shrinkage values of HVSCM-SCC were compared to prediction models proposal by AASHTO LRFD (2007), ACI-209R (2009), and AS 3600 (2009) to ensure the validity of these models for HVSCM-SCC.

KEYWORDS

Ecological, HVSCM-SCC, Accelerated curing, Creep, Shrinkage.

INTRODUCTION

Climate change is an issue and starts to concerning the world's environmental. Concrete is by far the most widely consumed resource in the world with water being the only resource to exceed it. In general, concrete is a mixture consists primarily from cement, sand, coarse aggregate, and water. The principal cementitious material in concrete is Portland cement .However, about 50% of the total CO2 emitted in construction of concrete structures comes from use of Portland cement. By reducing the cement content, CO2 emissions of concrete and energy consumption are reduced (Fennis *et al*. 2011). Also, with development of construction in last decades, the principle materials during processing cement have been increased. It should be taken into account that the natural resource employ in concrete are finite. Therefore, the civil engineers would have to consider the three aspects (reduce, reuse, and recycle) in all aspects of any construction of concrete structural. In other words, the sustainable of construction needs to be taken into account. To improve the environment friendliness of concrete, Ecological concrete has become a reasonable solution to prompt this aspect of concrete. Ecological concrete could properly define as any concrete using waste materials in place of Portland cement or aggregate. These waste materials are by products from other processes material. Fly ash, slag, and silica fume are some of byproducts materials that use as supplementary cementitious materials to replace a portion of Portland cement and satisfy the aspect of sustainability. Furthermore, using the SCMs is considering economic and ecological disposal of millions of tons of industrial by-product that can be safely incorporated as cementitious materials in concrete.

SCC is an innovation concrete material used successfully throughout the world. It can be consolidated into every corner of a framework, purely by means of its own weight and without the need for mechanical consolidation (Daczko 2012). One of the solutions to satisfy flowability of SCC is by using sufficient amount of paste (Higher cement content) and to control the heat generation, portion of cement can be replaced with SCMs. Traditionally, up

to 25% of the cement can be replaced with SCMs. Exceeding this level is considered to be high volume SCM and appropriate testing should be conducted to ensure desired performance of concrete.

Creep and shrinkage are two important time-dependent properties of concrete. They are one of critical factors for design of structural members due to the length change over time (Brewe *et al*. 2010). Using high volume of supplementary cementitious material in self consolidating concrete could raise questions regarding the performance of this type of concrete. Differences in the amount of time dependent losses in this type of concrete are one of these questions. To answer some of these concerning, this study was conducted to understand the creep and shrinkage behavior of HVSCM-SCC. An experimental study has been conducted to determine the amount of creep and shrinkage strain. The measuring data has been compared with predictive equations from ACI 209R-09, AASHTO LRFD 2007, and AS3600 to determine whether these typical Equations used by design engineers can be applied to HVSCM-SCC under condition of construction local materials and different curing conditions.

EXPERIMENTAL WORK

Materials

Portland cement type I that conforms to the ASTM C-150 was used. A high calcium type C fly ash that meets the ASTM C-618 was used as a binder to produce concrete. Moreover, micro silica fume and hydrated lime type S were used in this investigation. The specific gravities of cement, fly ash, micro silica fume, and hydrated lime used were 3.15, 2.68, 2.3, and 2.5 respectively. Natural sand with 0.25 in (6.35 mm) maximum size was used as fine aggregate and 2.56 specific gravity. The coarse aggregate used in this study was 0.5 in (12.5 mm) maximum size a crushed stone dolomite and it had a 2.77 specific gravity. A commercially available HRWRA was also used to maintain the workability of self-consolidating concrete.

Mix Proportions

The focus of this study was to explore the effects of replacing various percentages of Portland cement with SCMs to develop a sustainable concrete with long term performance. The control mix used in this study was designed to have 10000 psi (69.8 MPa) of compressive strength at 28days. The water to binder ratio (w/b) and aggregate and cement content was held constant for all mixtures. A cementitious content of 850 pcy (504 kg/m3) was used. Depending on optimum packing density, the fine to total aggregate ratio was determined to be 0.52. Intensive Compaction Tester machine (ICT) was utilized to obtain the optimum packing density of aggregate that satisfy the self-consolidating requirements. Table 1. illustrates all mixtures of this study.

FABRICATION AND CURING:

A modified version of ASTM C512 (2010) "Standard Test Method for Creep of Concrete in Compression" was performed to determine the creep of 4x16 in. (100x406 mm) cylinders. Each specimen was placed in 4 x 16 in. (100x406 mm) polyvinyl chloride (PVC) pipes. Concrete was placed in one layer and optionally roded to eliminate any entrapped air voids. Two curing conditions were employed in this study to investigate the effect of curing regimes. For accelerated curing, hot water system was used to simulate steam curing of precast applications. The maximum temperature of concrete was not exceed 158 °F (70 °C) to prevent the risk of delay attringite formation. The temperature rise during accelerated curing was limited to 68°F (20 °C) and also rate of cooling was limited to 68°F (20 °C) in compliance with AASHTO 2007. A preset period of not less than four hours was allowed before accelerated curing was applied. After accelerated regime had been completed, the specimens were demolded and stored in lab temperature room at 70°F (21 °C) until the time of tests. Moist curing specimens were covered with wet jute mats as soon as the concrete had set sufficiently that no marring of the surface or distortion resulted. After 24 hours, they were demolded and then stored into a moist curing room at 73°F (23 °C) temperature with 100 percent relative humidity. After 7 days curing, the specimens were stored in lab temperature room until the day of loading. At 28 days age, DEMEC points were outfitted with five-minute quick set epoxy on the specimens and preliminary readings were taken. Cylinders were loaded to 40 percent of the design strength. Six locations on each cylinder could be read to determine the change in strain over that length. The average of all of the readings was computed to be the total strain of the specimen. Figure 1-a displays the creep specimens setup used in this study.

To measure drying shrinkage, ASTM C157 was followed. A three prismatic specimens measuring 3x3x11.25 in (75x75x285 mm) were performed for each mix with a digital type extensometer as shown in Figure 1-b. The same curing regimes above were conducted for shrinkage specimens. After 7 days, moist curing specimens were stored lab temperature room at 70°F (21 °C). Shrinkage was then measured. However, accelerated curing specimens were demolded after curing and preliminary readings were taken. Table 2 displays concrete curing conditions.

Table 2 Concrete Curing Condition.

Curing Method	Stage	Details
Accelerated Curing	I	Lab Temperature for 4 hours minimum after water-cement contact
	II	Temperature raised for 2 hours
	III	Stead Concrete temperature for 18 hours
	VI	Temperature decreased over 2 hours to lab temperature
	V	Air Curing in Lab Temperature 23 ± 2 °C until testing age
Moist Curing	I	Twenty four hours in molds with wet burlap at 23 ± 2 °C
	II	Moist room curing at 23 ± 2 °C until testing age

CREEP AND SHRINKAGE CODE MODELS

Overtime, several models have been proposed to predict creep and shrinkage in concrete structure. In this study, the measured data were compared to typical code models from ACI 209R-09, AASHTO LRFD 2007, and AS3600, to determine whether these equations used by design engineer can be applied to HVSCM-SCC. A brief discussion is presented below. For specific details of the code models, the specific reference should be sought out for review.

ACI 209R (2009)

The ACI 209 model was developed for conventional concrete in 1973 and modified by ACI committee 209 to predict creep and shrinkage at a given age under standard condition and correction factors for other than standard condition. This ACI model considers numerous factors including cement content and type, the aggregate ratio, slump, air content, curing regime and others.

AASHTO LRFD (2007)

The AASHTO LRFD model was based upon work undertaken by Tadros et al. (2003). The research work undertaken by Tadros specifically investigated creep and shrinkage of high-strength concrete since earlier creep and shrinkage models were developed based upon conventional concrete data. The 2007 AASHTO LRFD model, based upon the 2003 study considers volume to surface ratio, relative humidity, and various age and loading aspects respectively.

AS 3600 – 2009

The AS 3600, creep and shrinkage models, includes correction factors for the type of environment, maturity of hardened concrete, and time. The environmental factor considers climates ranging from arid to tropical / near-coastal. Concrete strength is also considered through a basic creep coefficient and calibration factors.

TEST RESULTS AND DISCUSSION

Fresh and hardened properties

Test results of slump flow, T50, J-Ring, L-Box, density, and temperature are presented in Table 3. The mixtures with SCMs exhibited better rheological properties than 100% cement mixture. Mechanical properties "Compressive strength, modulus of elasticity, tensile splitting, and modulus of rupture", were conducted according to ASTM specification. Table 4. illustrates the mechanical properties results at 28 days of both accelerated and moist curing regimes. The compressive strength of tested mixtures was monitored at various ages 1, 3, 7, 28, 56, and 3 months as shown in Fig 3. It was found that, in general, each mix developed high early strength for accelerated curing. However, moist curing mixes performed high strength than accelerated over late ages. As anticipated, the compressive strength of HVSCMs mixtures was lower than 100% cement mixture.

Table 3 Measured rheological Properties.

Rheological properties	Unit	Mixtures			
		M1	M2	M3	M4
Slump Flow	in	27.0	26	26	25.5

a) Accelerated Curing b) Moist Curing

Figure 3 Compressive strength results at different curing regimes.

Shrinkage and Creep

Shrinkage and creep reading were taken until age 170 days. As can be seen in Figure 4, total strain of shrinkage and creep together verses elapsed time was drawn for all mixes. In general, it can be interpret that the mixes with high SCM exhibited lower shrinkage values than 100% cement mix. Furthermore, incorporation hydrated lime with binder system reduces the drying shrinkage. However, there was not significant effect on creep results when hydrated lime involves in the binder system. On average, Mix 4 with 75% replacement level exhibited less volume changes than other mixes and that means incorporation of SCMs in the binder system leads to better volume change behaviour.

As shown in Figure 5-a, Moist curing mixes with 75 % replacement exhibited lower drying shrinkage than 60% replacement and mix with 100% cement. Increasing the hydrated lime replacement level and reduce silica fume from 10 to 5 %, reduced drying shrinkage by 20%. Accelerated curing mixes exhibited less drying shrinkage range between 7-50% than drying shrinkage of same mixes cured under moist curing condition as can be seen in Figure 5-b. However, regarding creep results, there was not clear picture about effect the accelerated cuing on creep behaviour.

Comparison with code models

As shown in Figures 6 and 7, measured drying shrinkage and creep coefficient at age 170 days were compared to empirical code models adopted by ACI-209R, AASHTO LRFD, and AS3600. Mixes M2, M3, and M4 under accelerated curing condition had lower drying shrinkage values than predicted by code models above. In other word, it can be said that, code models overestimated mixes with high volume SCMs. Under moist curing condition, ACI-209R, AASHTO LRFD, and AS3600 overestimated drying shrinkage of mixes with 75% replacement level (M3 and M4). The values obtained by the ACI-209R equations are not as accurate as possible due to the equation requirements and the fact that ACI-209R was developed for conventional concrete. Furthermore, ACI 209R underestimated creep coefficient values of all mixes. In general, it can be indicated that empirical equation of code models were waved to predict the creep coefficient of high volume SCMs concrete.

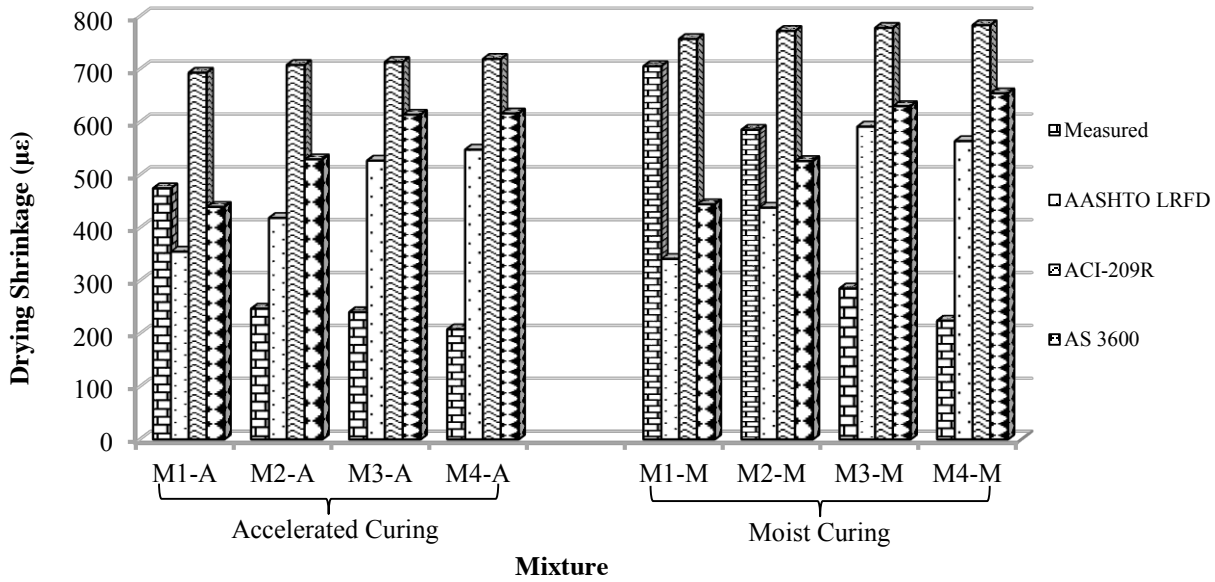

Figure 6 Drying shrinkage at age 170 days under different curing regimes

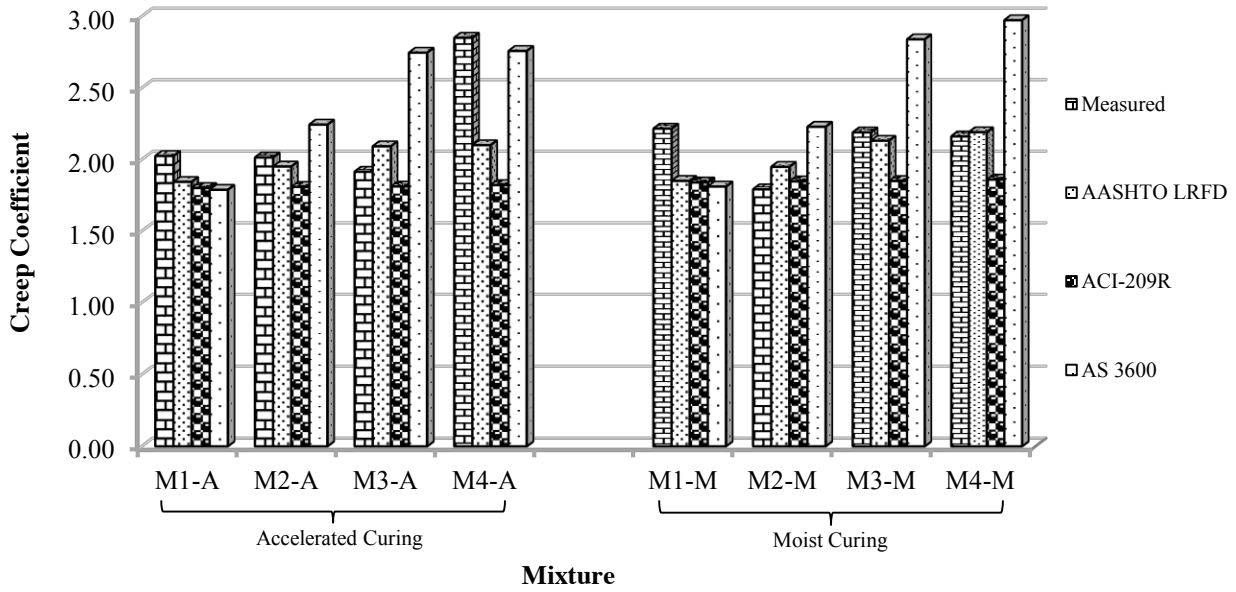

Figure 7 Creep coefficients of mixtures under different curing regimes (at age 170 days)

CONCLUSION

The purpose of this study was to compare volume changing overtime of mixes with different percent of SCMs as cement replacement and see the effect of accelerated curing on creep and drying shrinkage strains. Furthermore, the measured values were compared to the predicted code models adopted by ACI-209R, AASHTO LRFD, and As3600. Based on the results of this study, the following conclusions are presented:

- In this study, Mixes with 75% replacement level exhibited a low level of shrinkage and creep than other mixes.
- For mixes with 75% replacement, increasing the hydrated lime replacement level and reduce silica fume from 10 to 5 %, reduced drying shrinkage by 20%. Reduce in shrinkage is due the fact that lime intend to retain the surplus water of the paste matrix. As result, there is no more free water for drying.
- In general, the highest shrinkage and creep levels were observed in mixes with 100% cement cured under mist curing regimes.
- Accelerated curing mixes exhibited less drying shrinkage range between 7-50% than drying shrinkage of same mixes cured under moist curing condition at 170 days.
- Mixes M2, M3, and M4 under accelerated curing condition had lower drying shrinkage value than predicted by ACI-209R, AASHTO LRFD, and AS3600.
- ACI 209R underestimated creep coefficient values of all mixes due to the equation requirements and the fact that ACI 209 was developed for conventional concrete.

ABSTRACT

The proposed parallel state transformation procedures (PSTP) of fiber beam-column elements and multi-layered shell elements, combined with the parallel factorization of Jacobian (PF), are incorporated into a finite element program. In PSTP, elements are classified into different levels of workload prior to state determination in order to balance workload among different threads. In PF, the multi-threaded version of OpenBLAS is adopted to compute super-nodes. A case study on four super high-rise buildings, i.e. S1~S4, has demonstrated that the combination of PSTP and PF does not have any observable influence on computational accuracy. As number of elements and DOFs increases, the ratio of time consumed in the formation of the Jacobian to that consumed in the solution of algebraic equations tends to decrease. The introduction of parallel solver can yield a substantial reduction in computational cost. Combination of PSTP and PF can give rise to a further significant reduction. The acceleration ratios associated with PSTP do not exhibit a significant decrease as PGA level increases. Even PGA level is equal to 2.0g, PSTP still can result in acceleration ratios of 2.56 and 1.92 for S1 and S4, respectively. It is verified that it is more effective to accelerate analysis by reducing the time spent in solving algebraic equations rather than reducing that spent in the formation of the Jacobian for super high-rise buildings.

KEYWORDS

State transformation procedures, super-nodal Cholesky factorization, super high-rise building, parallel computing, OpenBLAS, nonlinear dynamic analysis, computational efficiency.

INTRODUCTION

Nonlinear dynamic analysis is a powerful tool for the assessment of seismic performance of structures under strong dynamic excitations, e.g. earthquakes. The standard simulation approach is to discretize the time-continuous governing equations by time integration methods then solve them via iterative algorithm (Bathe 1996). Since analytical time step or time interval, Δt, is generally small and iterations may be required within a step, the formation of real-time tangent stiffness matrix (also called the Jacobian) and solution process of system equations usually causes expensive computational cost. For large structures with a huge number of elements and degrees of freedom (DOFs), e.g. super high-rise buildings, such cost might be too high to be tolerable for design purposes although computer hardware is updated contemporarily.

Some parallel computing techniques were adopted to reduce computational cost from two aspects. Parallel direct (Cho and Hall 2012) or iterative solvers (Balay et al. 2014) are applied to accelerate the solution of system equations while the parallelized state determination of elements (Liu et al. 2007) is used to accelerate the formation of the Jacobian. Computational efficiency and convergence of iterative solvers are highly dependent on a pre-conditioner selected which is also closely related with the characteristics of the Jacobian. For super high-rise structures having various structural systems, direct solvers are more attractive because of excellent stability. Some parallel direct solver packages have been developed, e.g. MUMPS (Amestoy et al. 2001), SuperLU (Li 2005), and PaStiX (Hénon et al. 2002). The parallelized state determination of elements can be easily implemented (Yang et al. 2014). However, extra considerations should be taken in the treatment of unbalanced computational workload among different types of elements. Even within a certain type of elements, unbalance in workload can also exist between processed elements and unprocessed elements, if the state transformation procedures (STP) (He et al. 2015) are applied. Other than the above-mentioned two approaches, the domain decomposition methods (DDMs) (Smith et al. 1996; Sotelino 2003) directly divide the solution domain of concern into several subdomains and then assign one thread to each subdomain. In this way, the time consumed both in the process of the formation of the Jacobian and the solution of system equations can be saved

simultaneously (Yang and Hsieh 2002; Yang et al. 2012). Nevertheless, sometimes it is difficult to balance the workload among subdomains.

Performance of all the parallel computing techniques are highly related to the configuration of computer hardware, e.g. multi-core processors, multiple local computers (McKenna and Fenves 2007), high performance graphics processing units (GPU) (Papadrakakis et al. 2011), etc. Inter-process communication between threads may be an obstacle in parallel computing, especially on multiple local computers and GPUs. Data transmission between threads can be avoided in shared memory multi-processing on multi-core computers, which is not difficult for computerized implementation. Moreover, shared memory multi-processing is based on either open Multi-Processing (OpenMP) (Amritkar et al. 2012) programming language or POSIX Threads (Pthreads) (IEEE Std 1003.1c-1995) programming language. These accessible programming languages can be embedded in source codes and have been applied in many areas (Brown and Sharapov 2007).

This paper aims at developing some optimized shared memory computing procedures that to be implemented on personal computers for nonlinear dynamic time-history analysis for super high-rise buildings. An optimized STP-based strategy for the parallel state determination of elements is proposed to accelerate the formation process of the Jacobian, while the super-nodal Cholesky solver from CHOLMOD (Chen et al. 2008) is accelerated with multi-threaded OpenBLAS (Zhang et al. 2012) in order to solve the linear algebraic equations more efficiently. The characteristics of nonlinear dynamic analysis for super high-rise buildings will be discussed prior to the introduction of these procedures. The effects of some factors, e.g. peak ground acceleration (PGA) level, the number of DOFs and the number of elements, on computational efficiency are investigated.

PARALLEL COMPUTING STRATEGIES

Basic Procedures

The dynamic equilibrium of a nonlinear system can be expressed as the followings:

$$\boldsymbol{p}(t)-\boldsymbol{f}_{\mathrm{S}}\left(\boldsymbol{x}(t)\right)-\boldsymbol{f}_{\mathrm{D}}\left(\boldsymbol{x}'(t)\right)-\boldsymbol{f}_{\mathrm{I}}\left(\boldsymbol{x}''(t)\right)=0 \tag{1}$$

Where, $\boldsymbol{x}$, $\boldsymbol{x}'$ and $\boldsymbol{x}''$ are the vectors of displacements, velocities and accelerations of a system, respectively; $\boldsymbol{f}_{\mathrm{S}}$, $\boldsymbol{f}_{\mathrm{D}}$ and $\boldsymbol{f}_{\mathrm{I}}$ are the vectors of inertia forces, damping force and resisting forces, respectively; $\boldsymbol{p}$ is the vector of external excitations. Discretizing Eq. (2) with the ith analytical time step, Δt, will give the following incremental form,

$$\Delta\boldsymbol{p}_i-\Delta\boldsymbol{f}_{\mathrm{S}i}\left(\Delta\boldsymbol{x}_i\right)-\Delta\boldsymbol{f}_{\mathrm{D}i}\left(\Delta\boldsymbol{x}_i'\right)-\Delta\boldsymbol{f}_{\mathrm{I}i}\left(\Delta\boldsymbol{x}_i''\right)=0 \tag{2}$$

Eq. (2) can be simplified as the following general form by using any step-by-step time integration method,

$$F\left(\Delta\boldsymbol{x}_i\right)=0 \tag{3}$$

If the Newton-Raphson algorithm is applied to solve Eq. (4) and to obtain $\Delta\boldsymbol{x}_i$, the iterative procedures within an analytical time step can be expressed as:

$$\text{Obtain}\ \ \boldsymbol{s}_i^k\ \text{from:}\ \ F'\left(\Delta\boldsymbol{x}_i^k\right)\cdot\boldsymbol{s}_i^k=-F\left(\Delta\boldsymbol{x}_i^k\right) \tag{4}$$

$$\text{Set}\quad \Delta\boldsymbol{x}_i^{k+1}=\Delta\boldsymbol{x}_i^k+\boldsymbol{s}_i^k \tag{5}$$

Where, $F'(\Delta\boldsymbol{x}_i^k)$ is the Jacobian at the kth iteration during the ith analytical step, which can be computed by the time integration method selected; $\boldsymbol{s}_i^k$ is the increment of displacement vector after the kth iteration. For most time integration methods, e.g. the Newmark-beta method, $F'(\Delta\boldsymbol{x}_i^k)$ is a linear combination of tangent stiffness matrix, $\boldsymbol{K}$, damping matrix, $\boldsymbol{C}$ and mass matrix, $\boldsymbol{M}$, i.e.

$$F'\left(\Delta\boldsymbol{x}_i^k\right)=a_1\boldsymbol{K}_i^k+a_2\boldsymbol{C}_i^k+a_3\boldsymbol{M}_i^k \tag{6}$$

Where, constants, a_1, a_2 and a_3 are dependent on analytical step, Δt, and time integration method selected. A complete nonlinear dynamic time history analysis usually involves thousands of analytical steps and even more iterations, as illustrated in Figure 1. Thus, it is necessary to reduce computing time in the two time-consuming steps (see Figure 1) via some proper approaches.

Parallel Computing Strategy for STP

Fiber beam-column element (Spacone et al. 1996) and multi-layer shell element (Lu et al. 2015) are capable of capturing dynamic time-history nonlinear responses of structures excited by strong earthquakes. These elements can bridge microscopic material-level properties (e.g. stresses and strains) and macroscopic structure-level responses (e.g. deflection, story drift, base shear, overturning moment etc.) with desirable accuracy. However, computational accuracy is achieved at the cost of significant computation workload in material-level state

determination. It is prove to an efficient way to reduce the workload by using the state transformation procedures (STP) developed by He et al (2015), as illustrated in Figure 2. The STP is fully based on the understanding of sparse nonlinearity distribution in structures when they are undergoing strong earthquakes. It

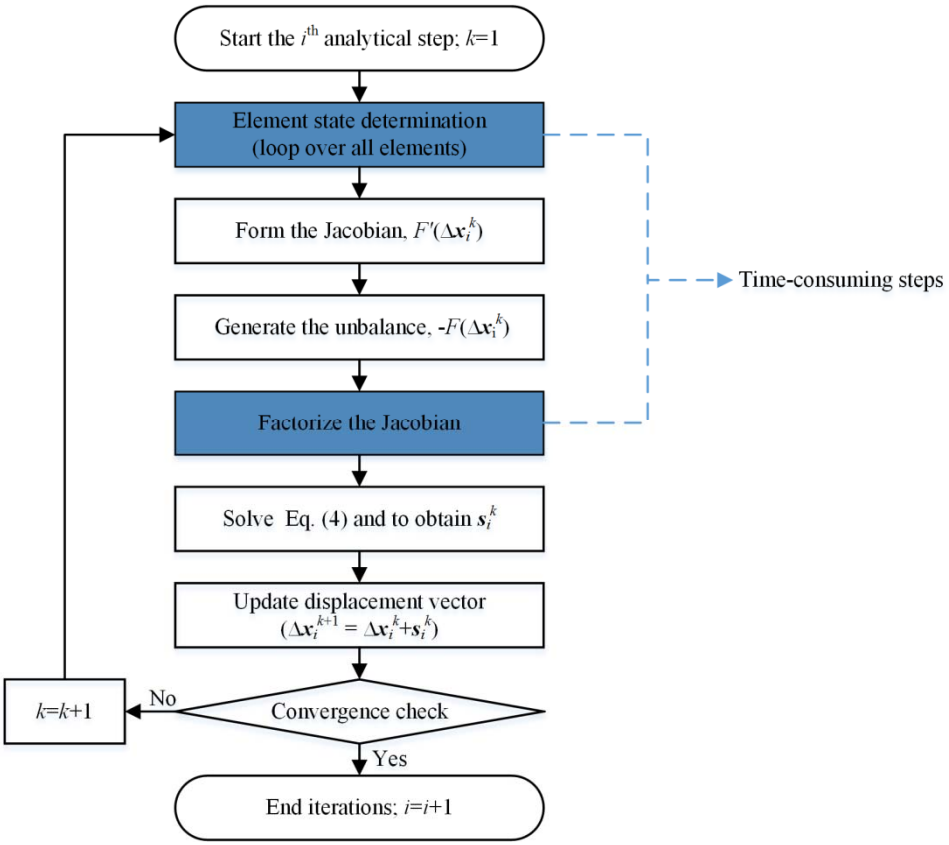

Figure 1 Iteration within an analytical step

assumes that sections at integration points in fiber beam-column elements and multi-layer shell elements have three states, i.e. initial state, elastic state and nonlinear state. The state determination of initial state and nonlinear state at integration points is carried out in a traditional way, i.e. from material level. Once initial state is determined, the subsequent determination of sections can override material-level computation in elastic state. All sections in this state are simply simulated by predetermined linear resisting force models until nonlinearity occurs. Once nonlinearity develops, the linear models will be replaced with those determined by corresponding nonlinear sections. Initial tensile cracking, nonlinear compression or yielding of steel can be all regarded as the critical limit of elastic cross sections. Beyond the limit, the sections will not behave linear elastic any more. Such nonlinearities developed in a cross section always start from some specific locations, e.g. corner point in a rectangular section or the outmost layer in a shell element. These locations can act as monitoring points for the determination of critical elastic limit.

The above-mentioned STP can be combined with parallel processing technique (PSTP) to achieve higher acceleration. However, thread allocation should be optimized to avoid thread wait. The unbalance in computational workload arises from two aspects when the STP to accelerate the state determination process of elements. One is from different time consumed in the determination of fiber beam-column element and multi-layered shell elements. The other is from different number of nonlinear sections among elements. Thus, the so-called level-to-level parallel processing scheme is proposed. That is, elements are classified into different levels of workload, as illustrated in Figure 3, prior to state determination according to the number of nonlinear sections at integration points develop within an element. n, n_f and n_s shown in Figure 3 denote the number of super-modes (to be introduced later), nonlinear sections in a fiber beam-column element and a multi-layered shell element. For instance, a fiber beam-column element with three nonlinear sections can be classified as Level 3 while Level 0 indicates zero nonlinear sections within an element. Parallel computing is carried out by using the dynamic schedule of OpenMP. In this way, workload among different threads is basically balanced.

Parallel Computing Strategy for LL^T Factorization

In most cases, the Jacobian is a sparse and symmetric positive definite matrix. Thus, the sparse Cholesky factorization (the $\boldsymbol{LL}^{\mathrm{T}}$ factorization) method can be applied to determine the increment of displacement vector after the kth iteration, $\boldsymbol{s}_i^k$, by the following equations:

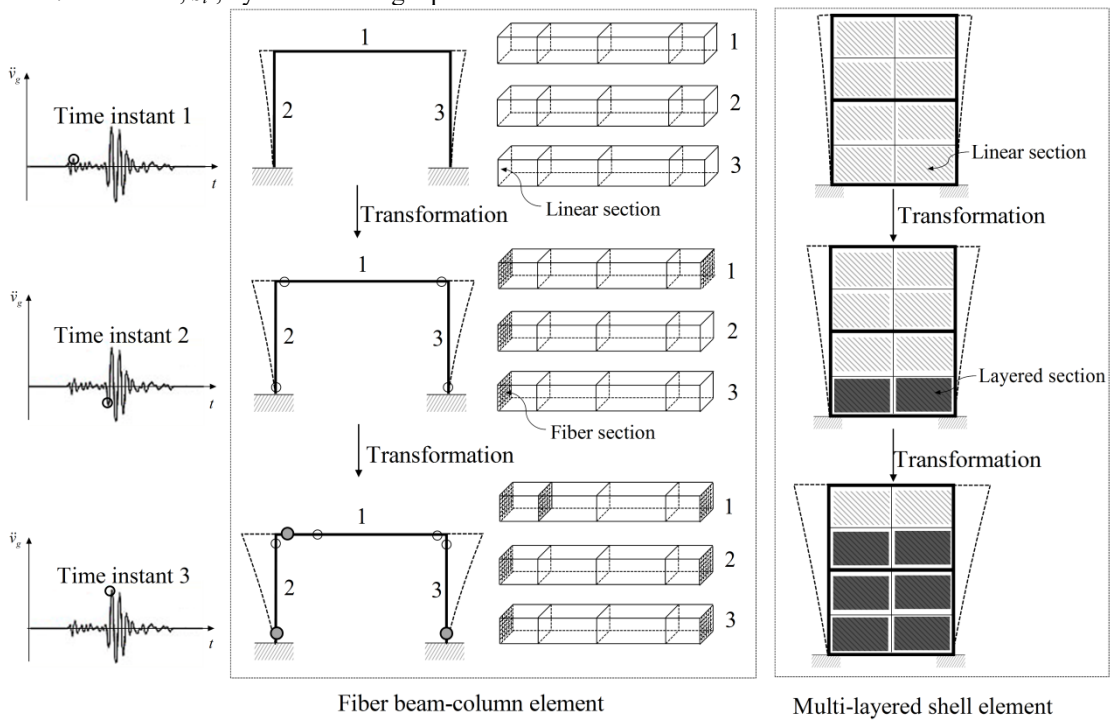

Figure 2 Concept of element state transformation (STP)

$$\text{Obtain } \boldsymbol{L}_i^k \text{ from: } \quad F'\left(\Delta \boldsymbol{x}_i^k\right) = \boldsymbol{L}_i^k \boldsymbol{L}_i^{k\mathrm{T}} \tag{7}$$

$$\text{Obtain } \boldsymbol{y}_i^k \text{ from: } \quad \boldsymbol{L}_i^k \boldsymbol{y}_i^k = -F\left(\Delta \boldsymbol{x}_i^k\right) \tag{8}$$

$$\text{Obtain } \boldsymbol{s}_i^k \text{ from: } \quad \boldsymbol{L}_i^{k\mathrm{T}} \boldsymbol{s}_i^k = \boldsymbol{y}_i^k \tag{9}$$

The super-nodal method (Rotkin and Toledo 2004) can be utilized to accelerate the factorization in Eq. (7), in which a set of super-nodes are computed through exploiting dense matrix kernels, i.e. the BLAS (Lawson et al. 1979). Some efficient BLAS libraries, e.g. Intel® Math Kernel Library (Intel® MKL) (Intel Corporation 2015), OpenBLAS and cuBLAS (NVIDIA Corporation 2015) are available. The former two are fully optimized for multiprocessing in Intel® CPUs. The last developed based on CUDA (NVIDIA Corporation 2015) is the GPU-accelerated version of complete standard BLAS library. With proper configuration of computer hardware, the three BLAS libraries have better performance than the standard serial BLAS. CHOLMOD is chosen herein to perform the super-nodal $\boldsymbol{LL}^{\mathrm{T}}$ factorization and the multi-threaded version of OpenBLAS is adopted to compute super-nodes. Thus, such factorization process can be parallelized (PF). As depicted by Figures 3, the step of numerical factorization is accelerated with multi-threaded OpenBLAS.

COMPUTERIZED IMPLEMENTATION

As one of open-source finite element programs, OpenSees (Mazzoni et al 2015) has been shown to be a powerful tool for performing nonlinear dynamic analysis of buildings and bridges and has become more and more popular in the field of earthquake engineering. However, some classes associated with elements in OpenSees have static member variables which are not compatible with shared memory parallel computing. Due to some reason, part of code in OpenSees has not been released so far, making an obstacle to realize PSTP. Thus, the above features are implemented into a new parallel finite element program using C++ program language. Some open-source codes available are incorporated into the program. The uniaxial materials of concrete and steel, i.e. Concrete02 (Hisham and Yassin 1994) and Steel02 (Filippou et al. 1983), as well as shell element ShellMITC4 (Dvorkin and Bathe 1984), are adopted from OpenSees (Mazzoni et al 2015). Eigen (Benoit and Guennebaud 2015) is chosen to handle basic matrix manipulations. Both the simplicial method and the super-nodal method in CHOLMOD are selected to perform sparse Cholesky factorization and to solve algebraic equations. Multi-threaded OpenBLAS is used to accelerate super-nodal sparse Cholesky factorization in parallel. In addition, the well-known MCFT for 2D concrete material developed by Vecchio and Collins (1986), and Vecchio (1999) is combined with the ShellMITC4 to develop a nonlinear multi-layered shell element (Li 2015).

The framework and some basic modules of the program are shown Figure 4. The program is compiled and fully optimized with open-source GNU compilers. In addition, the Newmark-beta time integration and the Newton-Raphson iteration algorithm are applied.

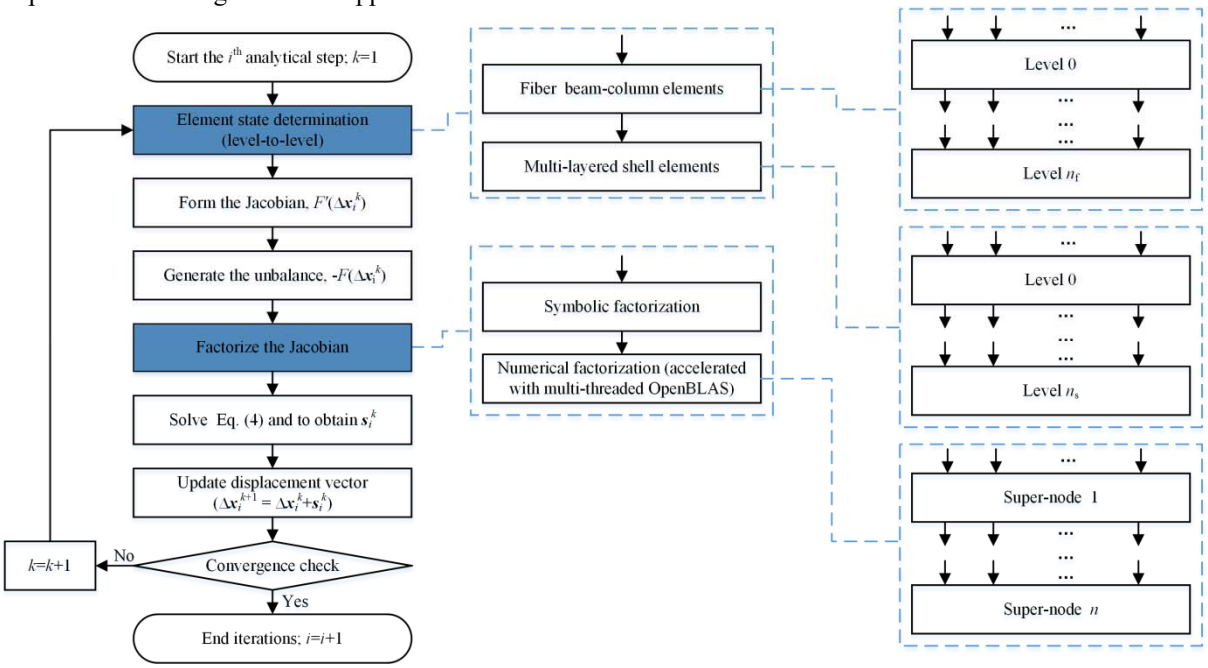

Figure 3 Basic procedures for PSTP and PF during an analytical step

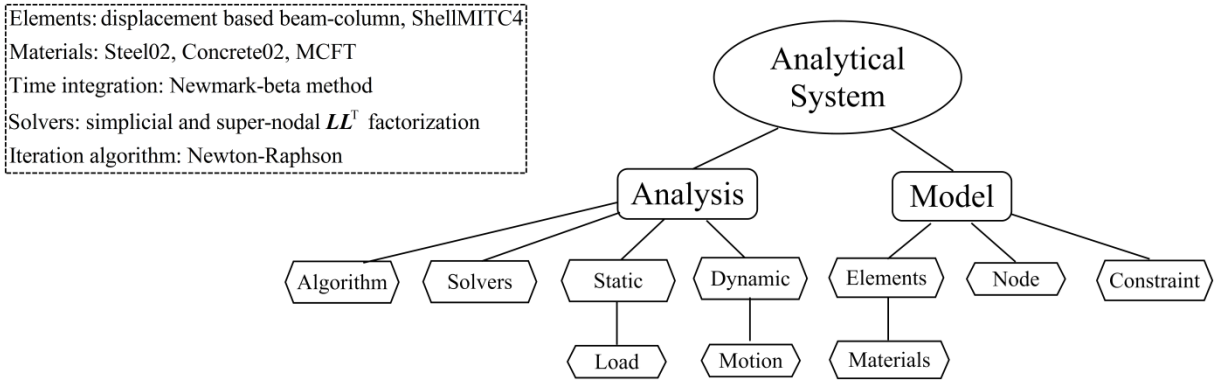

Figure 4 Basic modules of the program

CASE STUDY

Four super high-rise buildings, S1~S4 as illustrated in Figure 5, are selected to assess the performance of PSTP and PF. Both PSTP and PF have four threads. Structural walls, floors and ramps in S1~S4, and mega columns in S4 are modeled by multi-layered shells (red areas in Figure 5), while the rest components in S1~S4 are modeled by fiber beam-column elements (blue lines in Figure 5). A Dell Optiplex 9010 personal computer with a quad-core Inter I7-3770, 32GB main memory, and Linux Ubuntu 14.04 operating system, is used in the study. Three strong ground motions, i.e. Northridge earthquake at Station MUL009, Duzce earthquake at Station BOL000 and Hector earthquake at Station HEC000 (PEER 2015), with two horizontal components are selected as external excitations.

Computational Accuracy

Figures 6 and 7 illustrate some results of S1 from nonlinear dynamic time history analysis by using the program with PSTP and PF, and OpenSees (Mazzoni et al 2015) that combines the PlaneStressUserMaterial with ShellMITC4 (Dvorkin and Bathe 1984; Lu et al. 2015). The PGA levels of the principal components of three are scaled to 1.0g. Figures 6 and 7 show the top displacement time history response and the distribution of the

maximum inter-story drift ratios along structural height, respectively. The results between the program and OpenSees agree very well with each other.

Computational Efficiency (PGA=1.0g)

Model	Heihgt(m)	No. of Elements	No. of DOFs
S1	258.0	18030	37002
S2	333.0	18110	81660
S3	596.2	45964	156984
S4	688.8	93638	272130

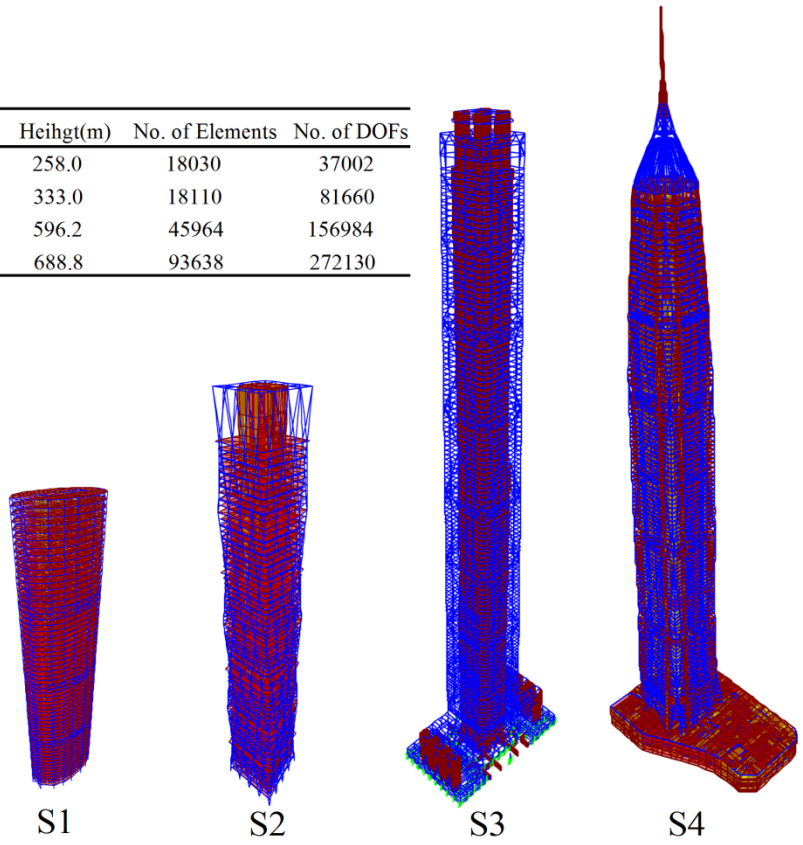

Figure 5 Numerical models

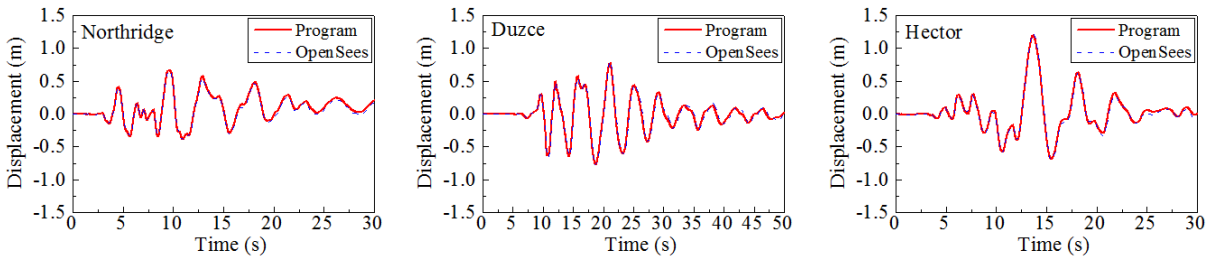

Figure 6 Top displacement time histories of Structure S1

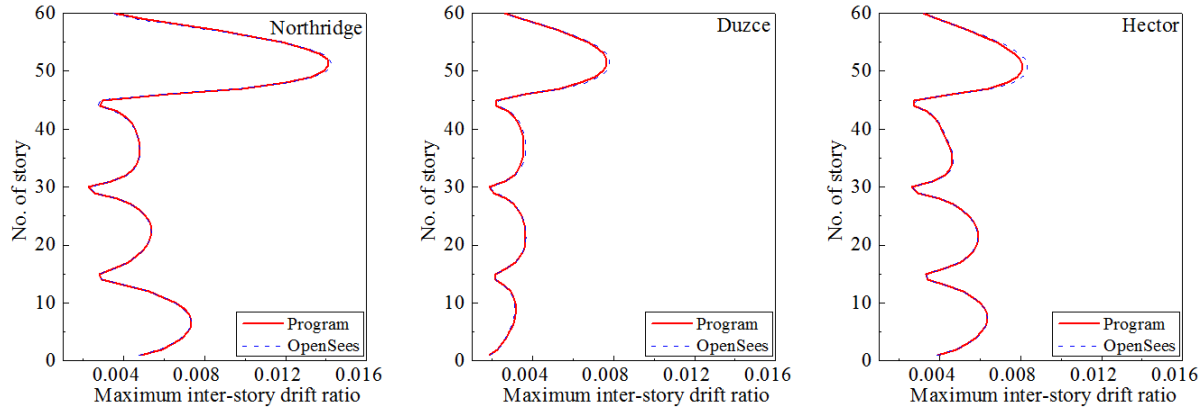

Figure 7 Distribution of maximum inter-story drift ratios of S1

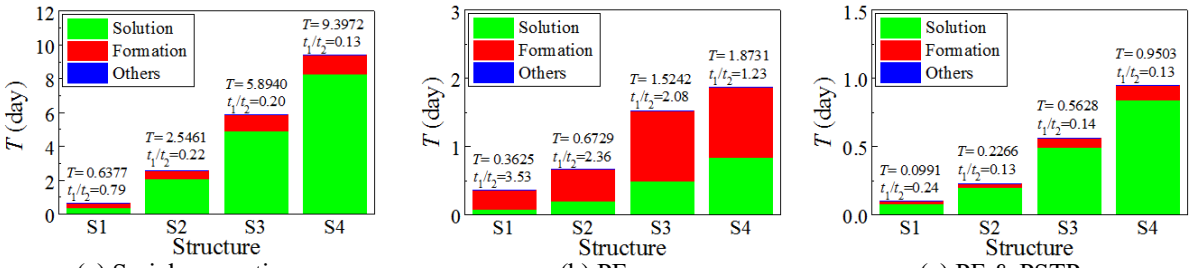
The computational efficiency of PF and PSTP is compared with traditional serial computing on four super high-rise buildings under Northridge earthquake with a scaled PGA level equal to 1.0g in principal component. Time consumed in the formation of the Jacobian, i.e. t_1, including mainly element state determination, and the solution of algebraic equations, t_2, are recorded during time history analyses, as illustrated in Figure 8 in which T represents total time consumed. As discussed previously, most of time is consumed in the formation of the Jacobian and the solution of algebraic equations in any case. As number of elements and number of DOFs increases, T, or total workload obviously increases. Because t_1 increases approximately linearly with the number of elements while t_2 increases nonlinearly with the DOFs. That is, difficulties in solving algebraic equations using direct solvers rise super linearly, the ratio of t_1/t_2 tends to decrease as structural height increases. If time consumed in other aspects is ignored, i.e. $T=t_1+t_2$, the introduction of parallel solver can reduce t_2 from 3.91d to 0.40d on average. Combination of PSTP and PF can give rise to further significant reduction in computational cost, more than 10 times faster than traditional serial computing on average. Every element is much less computationally expensive due to the combination of the STP and parallel computing technique. However, the workload of solving algebraic equations, t_2, becomes dominant again with dual application of PF and PSTP although total workload has been dramatically reduced.



(a) Serial computing (b) PF (c) PF & PSTP

Figure 8 Time consumed using three computing strategies (Northridge earthquake)

Computational Efficiency (PGA=0.2g~2.0g)

The efficiency of STP is highly related with PGA level. To fully demonstrate the efficiency of PSTP, incremental dynamic analyses are performed on S1 and S4. Three other earthquakes, i.e. an artificial earthquake wave (AEW), Tabas earthquake and Landers earthquake are selected, with the PGA level of principal component varies from 0.20g to 2.0g. Although significant difference is seen from Figure 9 between S1 and S4, the acceleration ratios caused by PSTP, $S=T_{PF}/T_{PF\&PSTP}$, decrease within a relatively small range as PGA increase from 0.2g to 2.0g. The PSTP still can result in averaged ratios of 2.56 and 1.92 for S1 and S4, respectively. The ratios of S4 are generally smaller than those of S1, because t_1 of S4 occupies less portion than that of S1, as can be observed from Figure 8(b). Thus, for large structures like S4, it is more effective to accelerate analysis by reducing the time spent in solving algebraic equations rather than reducing that spent in the formation of the Jacobian.

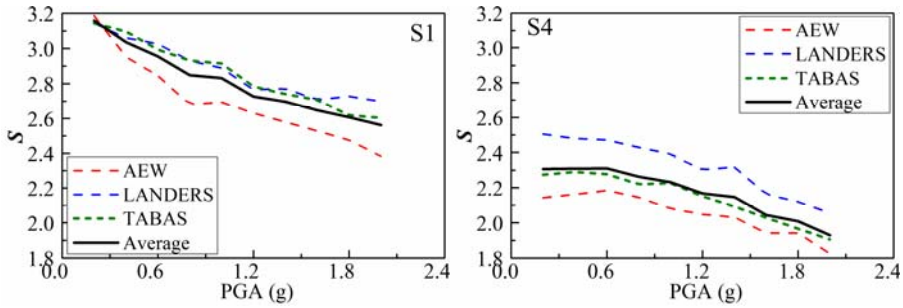


Figure 9 Acceleration ratios (PGA=0.2g~2.0g)

CONCLUSIONS

The proposed parallel state transformation procedures (PSTP) of elements combined with the parallel factorization of the Jacobian (PF) using multi-threaded OpenBLAS are incorporated into a finite element program. From the case study on the nonlinear dynamic time history analyses of four super high-rise buildings, i.e. S1~S4, the combination of PSTP and PF does not have any observable influence on computational accuracy. Most of time is consumed in the formation of the Jacobian and the solution of algebraic equations in all cases. As number of elements and DOFs increases, the ratio of time consumed in the formation of the Jacobian to that consumed in the solution of algebraic equations tends to decrease. Combination of PSTP and PF can give rise to significant reduction in computational cost, more than 10 times faster than traditional serial computing on average. The workload of solving algebraic equations will become dominant again although total workload is reduced dramatically with the dual application of PSTP and PF. The acceleration ratios associated with PSTP do not exhibit a significant decrease as PGA level increases from 0.2g to 2.0g. Even PGA level is equal to 2.0g, PSTP still can result in averaged ratios of 2.56 and 1.92 for S1 and S4, respectively. For super high-rise buildings, it is more effective to accelerate analysis by reducing the time spent in solving algebraic equations rather than reducing that spent in the formation of the Jacobian.

ABSTRACT

Light weight plastic spheres from recycled plastics have been commonly used in the design and construction of lightweight hollow-core concrete slabs. While this approach is regarded as an effective method to reduce the dead load of slabs and to increase the imposed load carrying capacity, limited technical information exists about the benefits of hollow core concrete slabs and their structural performance. A literature review on the engineering databases uncovered some awards and application articles on the technologies, but little analysis about its structural performance can be found. In this paper, *Strand 7* Finite Element Analysis in conjunction with *Rhinoceros* 4 3D CAD software was used to create composite FEA models of concrete slabs. These composite models were loaded to observe stresses and cracked section behaviour in both hollow-core concrete slabs and solid concrete slabs to determine the relative merits of hollow core concrete slabs over regular solid concrete slabs.

Hollow Cobiax core; Concrete slabs; FE analysis; Cracked and uncracked sections;

INTRODUCTION

Cobiax is a Sweden company specialising in the design and construction of lightweight structural hollow-core concrete slabs. Cobiax manufactures light plastic spheres from recycled plastics that may be embedded inside different concrete slabs. It is hypothesize that this technology would dramatically reduce the dead load of slabs and yet increase the imposed load carrying capacity.

Figure 1 A Cobiax slab before concrete pour

In a regular solid concrete slab, bending stress tends to cause slabs to deflect and ultimately fail. The majority of the bending stress is carried by slabs' extreme fibres on each tension and compression side. Cobiax works by lowering the slabs' dead load with an insignificant effect on the stresses at the extreme fibres. Based upon the reviewed literature, there was very little information available on the structural analysis of Cobiax-core concrete structures. The existing literature is mostly around articles on the basic parameters of the product and its awards for successful or innovative use. However, the most relevant references are discussed in this section.

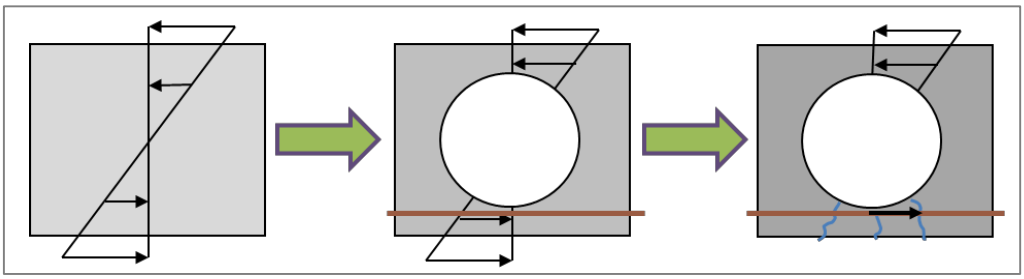

Figure 2 A slab in bending, and the concept behind Cobiax: solid slab (left), Cobiax slab (middle) and cracked Cobiax (right).

In 2007 the London Concrete Association released a paper about the construction of a library leading to the pattern of semi-precast Cobiax slabs (Stephenson, 2007). According to this reference, the construction time for the decks was reduced by abound 40%, dead load was reduced by 35% and carbon dioxide emissions were also cut by 1/3. Natural frequency of Cobiax slabs was investigated by Wolski et al. (2006). It was found that Cobiax slabs show relatively lower natural frequencies relative to the other types. Biaxial hollow slabs (including new types of voids) were investigated by Churakov (2014). The structural performance of the new slabs was obtained very similar to the solid slabs.

The environmental performance of precast slab with a void forming was examined by Hajdukiewicz et al. (2014), where the structural performance of Cobiax slabs were discussed. Bearing response of biaxial hollow-core slabs were set forth by Abramski et al. (2010). It was elaborated that shear strength of a two way hollow core slab is significantly smaller than a solid slab, while the bending capacity is gained by and large the same as a solid one. Marais (2009) expounded upon the economical application and the design adjustment factors of slabs with spherical voids. Cobiax was found to be quite appropriate where a flat soffit is needed in high multi-storey buildings – wherein large spans with a light load application are predominantly seen.

This paper aims at a Finite Element Modelling of Cobiax slabs, whereby the structural performance is assessed to quantify the relative structural responses of the solid slabs to be evaluated against their hollow core Cobiax counterparts. Promising results are obtained through this FE set of analyses which as a point of departure can inspire many researchers to get further into the present topic.

FE MODELLING

Modelling was carried out using a combination of *Strand 7* Finite Element Analysis package and *Rhinoceros 4* 3D CAD software. *Strand 7* has been chosen as the FEA package due to its elemental model setup. This setup allows *Strand 7* to be utilized in creation of the concrete body and steel reinforcement as beams attached to the nodes which also join and employ the required concrete in this study.

Due to the complex geometry of the created models, *Rhinoceros 4* was chosen as a 3D CAD modelling software. *Rhinoceros 4* (also known as *Rhino 4*) is a powerful CAD package which can easily generate different 3D models and has the capability of exporting created models as an *IGES* file type, which can be directly imported into the *Strand*. A typical cracked model with corresponding dimensions is presented through Figure 3.

Parameter	Dimensions (mm)
D	230
d	210
b	210
Sd	180
Cw	15
Ch	160

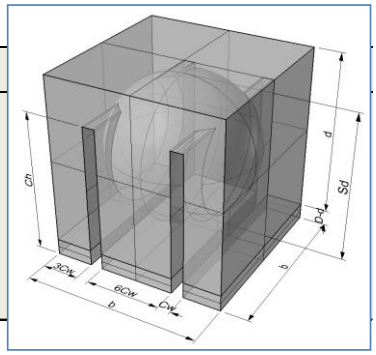

Figure 3 Geometry and dimensions of a typical cracked model.

UNCRACKED AND CRACKED MODELS

The slabs must be modelled such that the steel and concrete are sufficiently bonded along the length of the interface. To achieve this, a straight line of nodes is adopted within the concrete shell. Due to the random nature of Strand 7's solid auto-mesh facility, the steel cannot be modelled directly through the solid simulation. Rather, it has to be applied to the solid edge so that concrete can be applied to form the capping of the entire model (Figure 4).

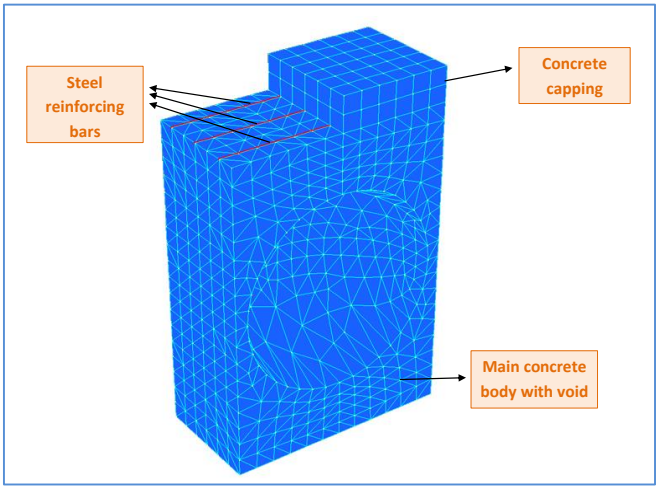

Figure 4 A basic concrete element (half section)

Once a concrete '*shell element*' has been modelled it can be exported from *Rhino 4* as an *IGES* file and in turn imported into the *Strand*. To auto-mesh the model surface, nodes and plate elements are created on each targeted face. The mesh is created as square 4 pt meshes so that a straight line of nodes is made, which properly allows the attachment of steel. Material properties are entered into *Strand 7* for each material, i.e. concrete (as bricks) and steel (as a beam element). Steel element is applied between nodes on the lower face of the solid by 'create element' linking each node along the path of the steel (Figure 5).

The select-by-region tool may be used to select each plate element on the lower face of the solid and extrude the plates to form bricks, which can essentially model the concrete capping on the lower side of the steel. With the assembled element of the desired slab configuration, the element can now be mirrored about the front axis of the solid to complete a full void. It has to be noted that all models were adopted as simply supported with only edge supports where the code calculated the deflections based upon the effective centre-to-centre span of the supports.

The same process is followed in transverse direction to complete simulation of a slab model. Unlike the solid slab though, the steel cannot be continuously fixed to the concrete on the slab's underside. In a cracked section, it is required that breaks in the concrete cause no tension stress in the concrete. This allows the steel to carry all tension loads. The nodes however, remain in a straight line such that the steel is modelled as a straight bar.

Figure 5 (a) cracked wireframe concrete section with a Cobiax sphere (b) cracked solid concrete section

RESULTS AND DISCUSSIONS

It is found that physical removing of predefined space from inside of the slabs does not lead to significant effect in the bending capacity as bending is predominantly carried at the extreme fibres. Shear however is carried across the entire depth of the slab in order that the increase in the shear stress is definitely quite proportional to the amount of employed material.

A modelled section was closely looked into via *Strand 7* and directly compared with a solid slab to determine the mentioned difference. Based upon the FEA results it appears that the shear capacity of a Cobiax section is approximately 55% lower than the shear capacity of a regular solid slab (Figure 6). It is fitting to note that the shear stress is not usually the limiting factor in structural slabs, while bending is a quite critical element. Notwithstanding this though, it is always required that the shear strength is verified in regions of high shear stress vulnerability.

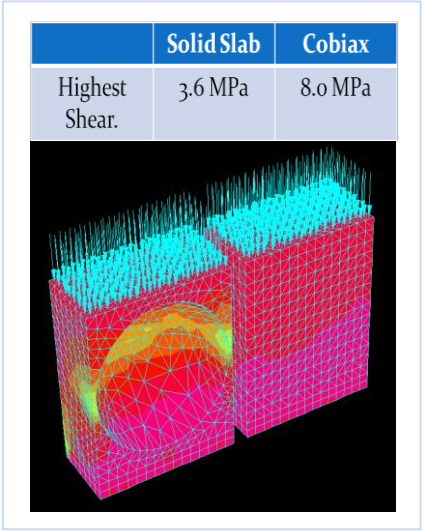

Figure 6 Cobiax and solid sections conducted in shear

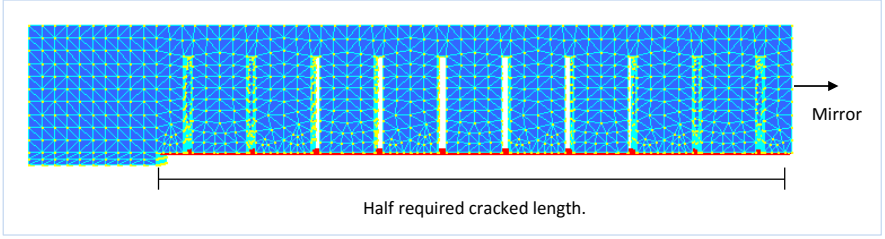
Figure 7(a) depicts the cracked slab with a half required length prior to the loading. Figure 7(b) clearly shows a distribution of tensile and compressive stresses within each concrete section bounded by the modelled cracks. This figure also shows the stress distribution in the steel bars respectively. As is seen, the localised regions of high stress are obtained where the crack has been lied in. In turn, areas in the vicinity of high stress zones are the locations where concrete is placed. It is believed that this reduction in the stress of the steel bars may highly reduce the total deflection of the entire model.



(a)

(b)

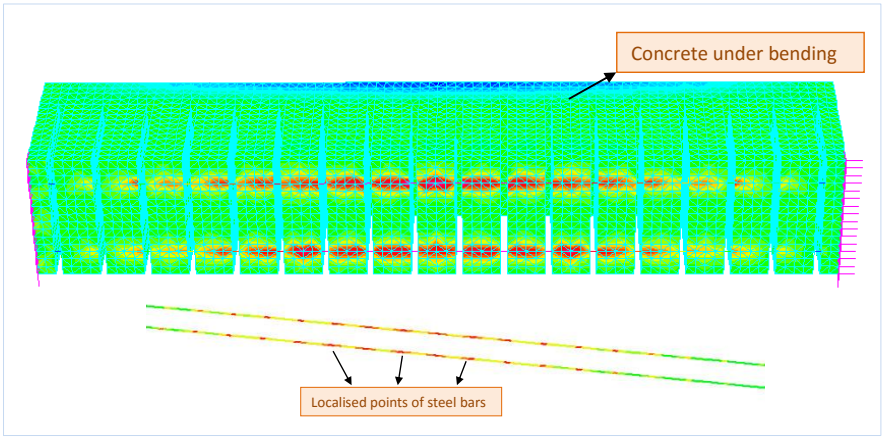


Figure 7 Cracked slabs before and after loading

Figures 8–10 compare three critical parameters of Cobiax and regular solid slabs. Stresses in the concrete, stress in the steel and deflections were evaluated for the new composite against the solid slabs. The results from each of the reinforcing cases favour hollow-core concretes as a reliable and yet cost-effective light weight structural member.

Composite modelling of concrete sections yielded very good results using a combination of *Strand 7* finite element analysis and *Rhinoceros 4* 3D CAD. Using simplified design formulas – as specified in the *Australian Concrete Standard* (*AS3600)* – the results of the non-Cobiax models were verified. Similarly, critical stresses were verified for the cracked models with a 15 mm mesh. With a mentioned mesh, which was used in most models, the *Strand 7* results were very close to the theoretically calculated results. All three critical stresses, i.e. concrete compression, concrete tension and steel tension, resulted in trivial differences comparing the present model with the theory.

It was found that regardless of the reinforcing configuration in a one-way slab, the use of Cobiax resulted in quite positive results. Cobiax achieved a 30% reduction in concrete used to cast the slab, and for the same imposed load, around 10% reduction in concrete compression stresses, steel tension stresses as well as deflection were achieved.

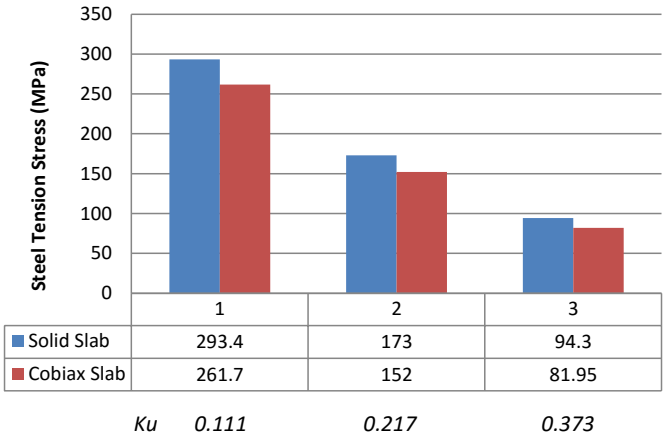

Figure 8 Steel tension stresses between Cobiax and solid slabs

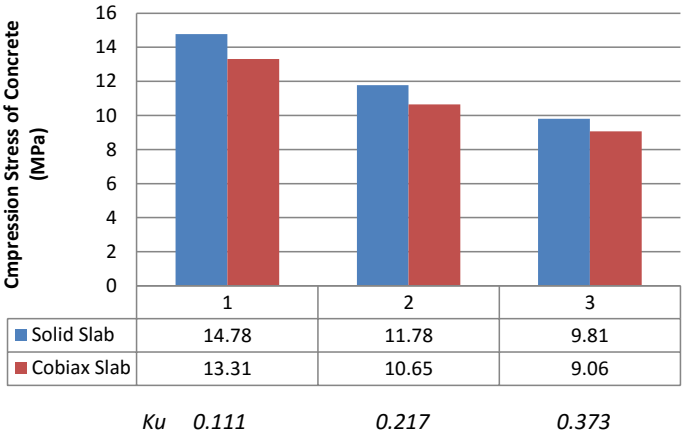

Figure 9 Concrete compression stresses between Cobiax and solid slabs

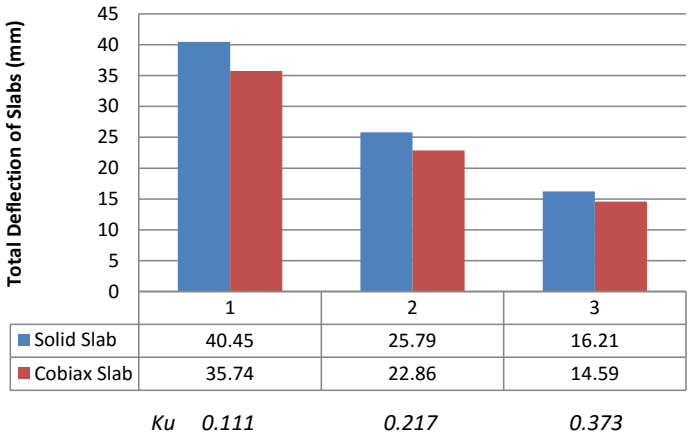

Figure 10 Total deflections of Cobiax and solid slabs

CONCLUSIONS

This paper aims at a Finite Element Modelling of Cobiax slabs, whereby the structural performance is assessed to quantify the relative structural responses of the solid slabs to be evaluated against their hollow core Cobiax counterparts. The summary of the results are outlines as:

It is found that removing the predefined space from inside of the slabs does not lead to significant effect in the bending capacity as bending is predominantly carried at the extreme fibres. Based upon the FEA results it appears that the shear capacity of a Cobiax section is approximately 55% lower than the shear capacity of a regular solid slab. The results from each of the reinforcing cases favour hollow-core concretes as a reliable and yet cost-effective light weight structural member.

Using simplified design formulas the results of the non-Cobiax models were verified. Similarly, critical stresses were verified for the cracked models with a 15 mm mesh which was used in most models. With a mentioned mesh, the *Strand 7* results were very close to the theoretically calculated results. It was found that regardless of the reinforcing configuration in a one-way slab, the use of Cobiax resulted in quite positive results. Cobiax achieved a 30% reduction in concrete used to cast the slab, and for the same imposed load, around 10% reduction in concrete compression stresses, steel tension stresses as well as deflection were achieved. In a nutshell, promising results of the present research can inspire many researchers as a point of departure to get further into the present topic.

ABSTRACT

The old linear and approximate second order analysis (known as P-Δ-only Analysis, which was first appeared in American LRFD 2010 and Hong Kong Steel Code 2005 and 2011) methods of design is considered non-sustainable as they have many limitations for future development such as those demonstrated by the leaning column paradox. Direct second order plastic P-Δ-δ analysis has been applied to the design of a number of structures in Hong Kong and Macau during the past decade since the introduction of the Hong Kong Steel Code in 2005 and 2011. The method could be extended to study the collapsing behavior of a building by an incremental-iterative procedure to determine the collapse load factor. This paper discusses the progress of the method in dealing with the design of buildings under various extreme event scenarios at ultimate limit state. The key issue related to this paper is that the study could now be conducted by a practicing structural engineer conveniently by the use of advance structural analysis computer method with robust element and nonlinear solution schemes. The method allows engineers to dictate more on the design of buildings and structures rather than relying on arguable assessment on structural performance under extreme events. Benchmark example on verifying structural analysis software is proposed in this paper. Finally, application of the method by a single element per member in the economical and safe design of a constructed steel structure without any use of effective length is demonstrated with saving in time and cost. The achieved reliability of the design by the new method will be discussed, which is believed to be pioneering in design technology in structural engineering.

KEYWORDS

Sustainable design, second-order direct analysis, second-order indirect analysis.

INTRODUCTION

Bare steel frames are widely used in the construction industry as they can span across large distances while being easy to construct. Failure modes of this structural form are not simply due to elastic buckling, material yielding or individual member buckling, instead it can be due to more complicate failure modes, which is the elasto-plastic buckling of members. The first-order linear elastic analysis, which has been widely used in the design of steel structures, is not able to predict the failure load accurately and reliably since most of the non-linear effects due to interactive buckling modes cannot be simulated. The use of second-order "direct" analysis can trace the behaviors and predict the failure load of the structures accurately up to the first plastic hinge for conventional "first-plastic hinge design" or the plastic collapse load for the "advanced analysis" in AS4100(1998). The inclusion of both P-Δ and P-δ moments and their associated imperfections are important in the analysis and would result in safer design since they are unavoidable in practice. Moreover, the second-order indirect analysis or the P-Δ-only analysis could only give the sway moment that can be found alternatively by using sway amplification factor multiplied to the bending moment from a linear analysis and it does not consider member buckling. Its limitation in application should be aware of. Using the rigorous second order direct plastic analysis, a steel building frame or other structures could be easily checked for stability and ultimate load capacity in a user-friendly and convenient manner. Fig.1 shows the load vs. deflection plot and thus the collapse load of the Vogel frame with lowest mid column removed or damaged completely, where it can be used to investigate the mechanism and load resistance under progressive collapse check resulted by a failed structural member. This checking can be done in a simple manner using a PC or desktop computer at minimal cost and maximum convenience using software such as NIDA.

Studies of bare steel structural system or the portal frame system covers specifically in this paper have been comprehensive because of its extensive uses (see, for example, Lim et. al 2005). In many countries such as the Japan and UK, a high proportion of construction steel material is used for the construction of portal frames for industrial buildings. Lim el al (2005) proposed a method of analysis and design mainly based on the Merchant-Rankine formula and the moment amplification approaches. Telue and Mahendran (2004) use a sophisticated finite element to study the response of portal frames and it appears that it could hardly be used for daily portal frame design with many load cases. Furthermore, these works mainly concentrate on single bay portals, while a more practical and economical design method allowing for plastic yielding and large deflection for general framed structures is not yet reported. This paper is aimed to resolve this problem.

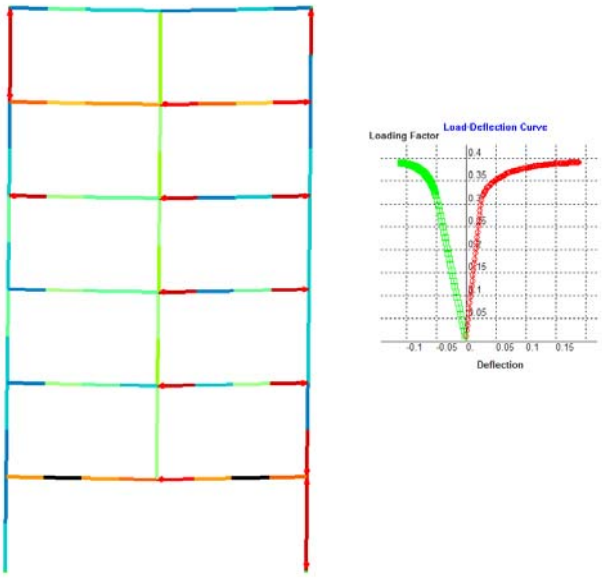

Figure 1 Plastic load resistance of the 6-storey Vogel's frame upon removal of the center lowest column

Different elements for nonlinear analysis have been proposed by many researchers. The stability function is one of the most popular methods used. The stability function allows the use of only one single element to model a member and gives an accurate result. However, the formulation of the stability function is too complicated and different forms of stability functions would be obtained under tensile and compressive axial forces which lead to loss of generality. Cubic element is also commonly used in nonlinear analysis to model the one-dimensional beam-column member used by researchers such as Meek and Tan (1984), Liew and Tang (2000), Albermani and Kitipornchai (2003) and so on. However, the element over-estimates or under-estimates when only one single element is used to model a member as demonstrated by Chan and Zhou (1994). The use of several elements to model a member leads to complexity in modeling and increase the computational time. Besides, the direction of member initial imperfection is not easy to assess. The use of pointwise equilibrium polynomial (PEP) function proposed by Chan and Zhou (1994) allows the model of one element per member model in most practical cases with a provision of accurate result. The P-Δ and P-δ moments, initial and geometry imperfection and material nonlinearity can be included in their method. Separating the compressive and the tensile load cases with the matrix being valid for positive, negative and zero axial force is not needed in their approach. Moreover, Chan and Zhou (1995) included the equivalent initial imperfection, which simulates the effect of geometric imperfection and residual stress, into the PEP element formulations to complete the modeling for buckling and sectional action computation. In this paper, the pointwise equilibrium polynomial (PEP) function is used. Simple columns with different boundary conditions and a two storey frames are analyzed and a practical transmission line tower is designed, which show the advantages and convenience of using the proposed second-order direct analysis method of design.

Second-order Direct Analysis Method of Design

The use of one element to model each member will not only saves the computational time which is especially important in large structures conveniently, it also includes member initial imperfection which is unavoidable in all members and structures. Ignoring imperfections may resulted to an unsafe design. The PEP element is

capable of modelling one member by using only one element in second-order analysis. The detailed element formation, tangent and secant stiffness matrix and the numerical method for analysis is summarized below.

Element Formation

The initial imperfection as shown in Fig.2 is assumed in the element as follows.

$$v_0 = v_{m0}\left(1-(\frac{2x}{L})^2\right), \quad -L/2 \le x \le L/2 \tag{1}$$

v_{mo} is amplitude of initial imperfection equal to the imperfection at mid-span and L is the length of the member.

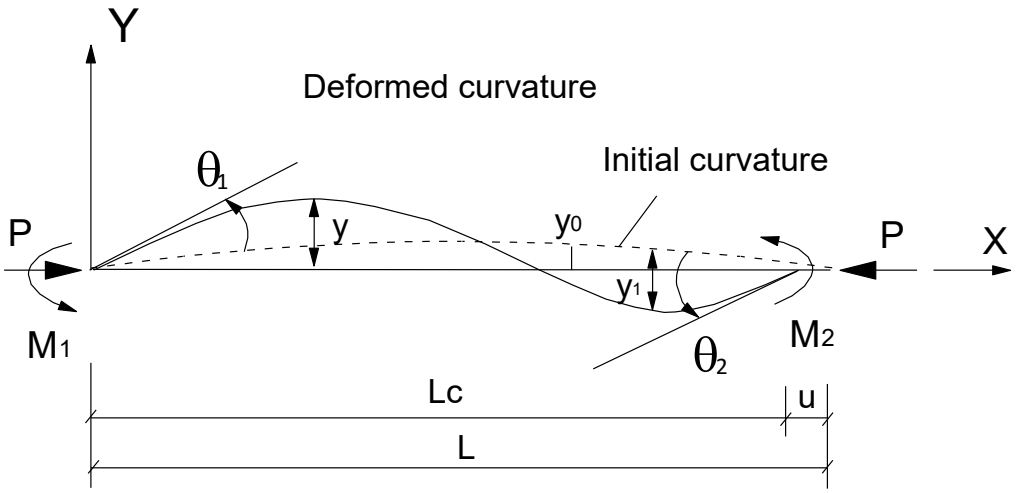

Figure 2 The beam-column element

The fifth order polynomial function given below with six coefficients can be solved by using six constrained equations,

$$v = a_0 + a_1 x + a_2 x^2 + a_3 x^3 + a_4 x^4 + a_5 x^5 \tag{2}$$

in which x is non-dimensional distance along the element, v_o is lateral initial imperfection,

Six constrained equations include the four equations in compatibility condition and two equations in equilibrium condition are used to solve the six coefficients in the polynomial function.

In equilibrium condition,

$$EIv'' = P\left(v+v_0\right) + M_1\left(\frac{x}{L}-\frac{1}{2}\right) + M_2\left(\frac{x}{L}+\frac{1}{2}\right) \tag{3}$$

$$EIv''' = Pv' + \frac{M_1 + M_2}{L} \tag{4}$$

In compatibility condition,

$$\text{At } x = -\frac{L}{2} \quad v = 0 \text{ and } v' = \theta_1 \tag{5}$$

$$\text{At } x = \frac{L}{2} \quad v = 0 \text{ and } v' = \theta_2 \tag{6}$$

in which E is Young's modulus of elasticity; I is second moment of area; v is lateral displacement due to applied loads; P is axial force; M_1 and M_2 are nodal end moments. Please note that the shape function derived by PEP element is valid for positive, negative and zero value of axial force.

The final displacement function about the axis passing through the two ended nodes can be expressed as,

$$v = N_1(L\theta_1) + N_2(L\theta_2) + N_0 v_{mo} \tag{7}$$

in which N_1 and N_2 are the shape functions for perfectly straight element and

$$N_o = -q\frac{(1-t^2)^2}{H_2}, \qquad H_2 = 48 + q, \qquad q = \frac{PL^2}{EI}$$

Secant and Tangent Stiffness Matrix

The secant stiffness matrix is used to check the equilibrium convergence, to compute the equilibrium error due to change in the geometry and to check the cross sectional strength. The secant stiffness matrix can be obtained by applying the stationary energy principle as follows:

The total potential energy function, Π, is given by:

$$\Pi = U - V \tag{8}$$

in which U is the strain energy and V is the external work done as:

$$V = \sum F_i u_i \tag{9}$$

in which F_i is the applied forces and u_i is the displacements.

The strain energy, U, can be expressed as:

$$U = \frac{1}{2}\int_L EAu'^2 dx + \frac{1}{2}\int_L EIv'' dx + \frac{1}{2}\int_L P\left(v'^2 + 2v'v_0'\right)dx \tag{10}$$

The tangent stiffness matrix used for prediction of the displacement increment can be found by second variation of the total potential energy function.

$$\delta^2\Pi = \frac{\partial^2\Pi}{\partial_{r_i}\partial_{r_j}} = \frac{\partial_{s_i}}{\partial_{r_j}} + \frac{\partial s_i}{\partial_q}\frac{\partial_q}{\partial_{r_j}} \qquad i,j = 1,2,3 \tag{11}$$

in which s_i and r_i are respectively the force and displacement vectors given by,

$$s = [M_1 M_2 P]^T \tag{12}$$

$$r = [\theta_1 \theta_2 e]^T \tag{13}$$

Section Capacity Check for Second-order Direct Analysis

The use of second-order analysis can included the P-Δ and P-δ effects automatically in the section capacity check equation, as a result, the individual member check is replaced by the section capacity check as:

$$\frac{P}{A_g p_y} + \frac{M_y + P(\delta_y + \Delta_y)}{M_{cy}} + \frac{M_z + P(\delta_z + \Delta_z)}{M_{cz}} = \phi \le 1 \tag{14}$$

In which, P is the axial force in the member, p_y is the design strength of the member, A_g is the gross cross-sectional area , M_y and M_z are the applied first-order moments about the y- and z- axes, M_{cy} and M_{cz} are the moment capacities about the y- and z- axes. $P(\delta_y)$ and $P(\delta_z)$ are the second order P-δ moments about the y- and

z- axes of which the consideration allows us to include automatically the bending effect due to axial force and second-order deflections, and $P(\Delta_y)$ and $P(\Delta_z)$ are the second order P-Δ moments about the two axes of which the consideration allows us to include automatically the bending effect due to axial force and second-order deflections.

Therefore, the estimation of effective length is not required as the P-Δ and P-δ effects have been included in the Eq.14 for section capacity check. Moreover, the initial imperfection is also included in analysis that the Perry-Robertson formula for imperfect columns can be directly applied in the integrated analysis and design procedure.

In the analysis procedure, a small load increment of, say 5 to 10% of the expected design load, is applied to the structure by an incremental-interactive procedure and the design load is attained when the section capacity factor φ in the Eq. 14 is equal to unity.

Numerical Method

Load control Newton-Raphson method combined the minimum residual displacement method (Chan 1988) and arch-length load control (Crisfield, 1980) is used and it is capable of tracing the path up to and beyond the limit point without numerical divergence. Minimum value for the equilibrium error for residual displacement in each interaction is guaranteed by using this method. This numerical method not only traces the pre-buckling behaviors of the dome, but it also charts the post-buckling load versus deflection curve.

Examples

Two examples are selected for application of the proposed method. The first example is a gable portal frame by Ziemian (1992). The second example is a project for transmission towers done by the authors utilizing the purposed method.

Ziemian's two-story frame

The two storey frame shown in Fig.3 is proposed by Ziemian (1992) as a calibration frame. He adopted both plastic hinge and plastic zone methods in his analysis and the geometrical dimensions are shown in Fig.3 and its detailed material properties are available in the original text (Ziemian, 1992).

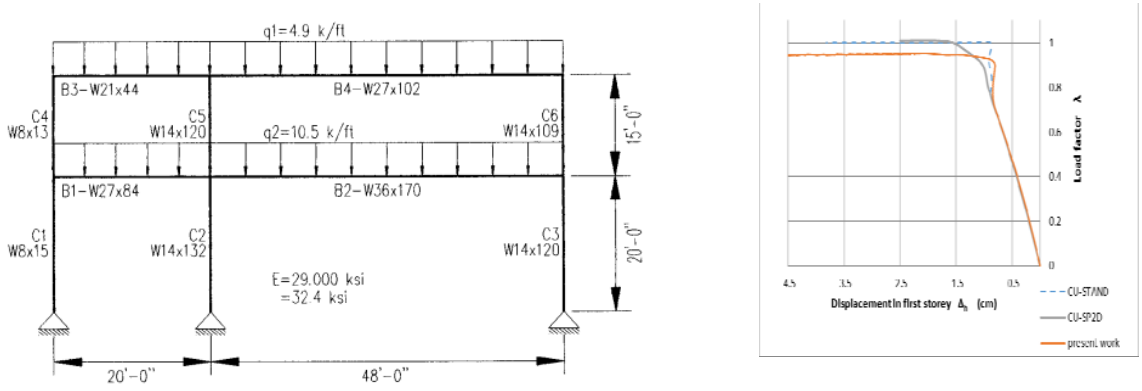

Figure 3 Comparison of the first story load-deflection response by Ziemian (1992) and NIDA(2015)

It can be seen in the comparison the present results are slighly conservative and it seems to be acceptable and preferrable in practical design. This conservatism is due to use of the linear moment-axial force interaction equation which underestimates the plastic capacity of a section. A more refined yield or plastic function could be adopted to more economize the design. On the other hand, the proposed method is simpler to use than the plastic zone method. Also, the plastic hinge method is based on the section capacity check which is easily found in design codes for the yield function of the section so engineers could have a better physical grasp of the yield condition for the yield section.

Another observation in this example shows that the present method converges very well in both elastic and plastic ranges. The problem of reaching divergence for nonlinear analysis in the past seems to have been overcome by the proposed method using the self-equilibrium element and the iterative scheme, which unfortunately unavailable in most frame analysis and design software in market.

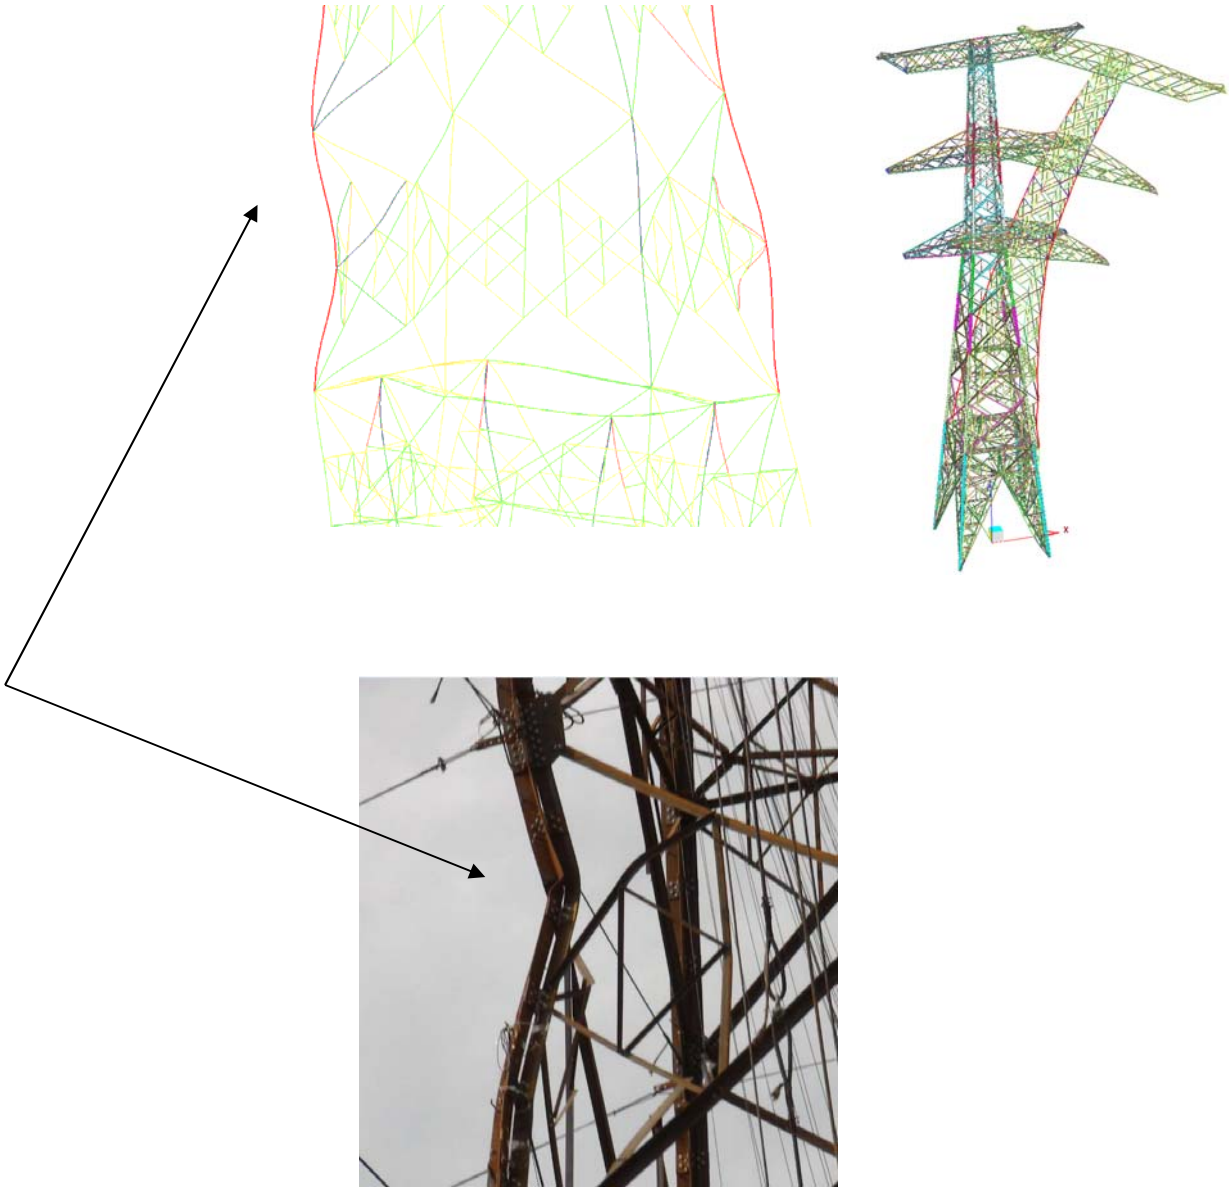

Figure 4 The tested and simulated tower in a completed project by authors

Simulation test of transmission line towers

Transmission line towers collapse quite frequently in different parts of the world, likely because of the wide spread use of inadequate second order analysis not allowing for member P-δ effect. When collapse, engineers in government departments in these countries will impose full-scale tests for the towers to ensure they would not collapse under the design loads so there have been a practice of testing towers in many countries.

On the other hand, some places like Hong Kong do not generally have problem in tower collapse therefore they do not require such physical tests. These places use nonlinear and full direct analysis for simulation of tower collapse to ensure they would not fail before reaching the design loads. To this, the authors were involved in a number of simulation tests for countries in countries in Southeast Asian. Using the plastic hinge approach, the method and the associated program NIDA is applied to practical simulation of transmission line towers in Hong Kong, China and Myanmar. Fig.4 below shows the analysis and test results using the actual material and geometrical properties in the test. The effects from material yielding, imperfections eccentric connections and slips are considered in the model. Interestingly, the numerical and test results give failure loads with 5%

discrepancy for several tested load cases and two types of tested towers. Fig.4 shows the failed tower in test and in our simulation with NIDA respectively.

CONCLUSIONS

The design method of Second-order Direct Analysis has been developed and applied to benchmark and practical examples. Unlike the old method where assumption of effective length is uncertain, change of stiffness due to the initial stress for members is ignored, the method can handle not only daily design under static loads, it could be extended rationally to other scenarios such as studies for progressive collapse, seismic design, fire engineering design using material properties under elevated temperature and so on. The concept results in a more sustainable solution and the uncertainties from the effective length method can be eliminated when dealing with design under truly ultimate or collapse limit state. The popularity of this method is showcased by the numerous projects in Hong Kong and Macau undertook by the authors.

ABSTRACT

In this paper, the nonlinear post buckling response of X-Braced Moment Resisting Frame (X-BMRF) systems are studied. The X-BMRF comprises of X-bracing diagonals attached to the moment frame by corner gusset plates to form the structural system acting as a dual frame. In common practice today, one of the X-bracing diagonal members is discontinuous, and a middle gusset plate is used to connect the diagonals to each other at the intersection. In this study, the effect of mid-connection details and different types/sizes of corner gusset plate connection are well measured to evaluate behavioral characteristics of the above systems. An accurate and robust three-dimensional finite element modeling of the above systems validated/verified against available test data and numerical simulation are demonstrated. Then, a number of X-BMRFs are designed and analyzed under monotonic (and cyclic) loading(s), and later ductility values and energy dissipation ratios of such systems are appraised. The results are used to evaluate the secondary yield mechanisms, probable failure modes, and to quantify the loading share of story shear when different rigidity ratios between the X-bracing and moment frame systems are deliberated. Finally, the results can provide a suitable ground to present a new set of balanced design criteria which can improve nonlinear performance and assure maximum system ductility of such system.

KEYWORDS

X-bracing, braced moment resisting frame, ductility, energy, balanced design, cyclic, yield, failure.

INTRODUCTION

Braced moment resisting frame (BMRF) systems are dual structural frame with both advantageous of moment resisting frame and braced frame systems. A BMRF can be typically exhibited by two types of its gusset-brace subsystem, *viz.*, diagonally braced moment resisting frame (DBMRF) and X-braced moment resisting frame (X-BMRF). Recently, the inelastic post buckling response of the DBMRF systems was thoroughly investigated in Lotfollahi *et al.* (2015). That research aimed at manifesting how, when, why, and where multiple secondary yield mechanisms and probable failure modes should be well evaluated through the DBMRFs to formulate a balanced dissipative performance, and to calibrate the system to execute a new and improved design criteria. The X-BMRFs, on the other hand, demonstrate rather complex behavior than the DBMRFs; furthermore, they exhibit excellent nonlinear performance, high stiffness and strength with a compact architectural form.

The seismic design requirements of a X-BMRF system are mainly affected by the cyclic behavior of the complete frame actions. As the early investigations in this area, Shepard (1972) tested very light X-braced frames that would qualify as tension only braced frame systems, Goal and El Tayem (1986) tested a series of idealized X-braced frames with angle bracings, and Tremblay *et al.* (2003) tested 10 X-braced frames with idealized pin frame connections. In all aforementioned cases, the frames fail to construct and simulate; therefore, the actual behavior of X-braced frames and the effect of moment frame system have not been fully considered.

A number of researches were performed on different special concentrically braced frame (SCBF) systems; however, the X-bracing configuration in some of them applied to more than a single story. Among them, Roeder *et al.* (2011a) conducted three full scale experimental setups to examine the nonlinear performance of one-bay, two-story split-X braced frame systems. Lumpkin *et al.* (2012) carried out another research on two experimental set ups of one-bay, three-story split-X braced frame systems to evaluate an improved inelastic seismic

performance with proper design detailing of more compact corner gusset plate connections, and a recommended clearance to perform balanced design of mid-span gusset plates. Besides, recent researches have illuminated more aspects of SCBF systems with X-brace configuration in a single story. Powell (2010) performed two tests on a single story X-braced frame to investigate the effect of X-bracing center splice details. Palmer *et al.* (2013) conducted a research program with a test matrix consisted of nearly full scale three dimensional, one-bay by one-bay, two story X-braced frame to examine a previously balanced design approach for failure modes of gusset plate connections in such systems, and to indicate the effect of out-of-plane demand.

The previous works have implied to the lack of implementation of a new and improved balanced dissipative behavior which can efficiently and economically elaborate on multiple yielding hierarchy and probable failure sequences in both the main frame and gusset-brace subsystems of X-BMRFs. To the best of authors' knowledge, there is yet no pragmatic approach, in spite of previous efforts (e.g., Palmer *et al.* 2012), to resolve the abovementioned shortages. In this study, we want to make a suitable ground to propose a new set of improved balanced design criteria during all stages of lateral loadings which can be able to remediate all the previous deficiencies in the design of X-BMRF systems. We drive the said criteria based on the non-dimensional formulation when the participation of all system constituents under cyclic loadings are prescribed. However, we aim to verify the proposed criteria under dynamic buckling analysis during the next work on multi story systems.

NEW BALANCED DESIGN CRITERIA

The following inequalities—i.e., originated from Lehman et al. (2008), extended by Roeder et al. (2011b) to diagonal bracing systems, and then utilized by Palmer et al. (2012) for X-bracing systems—provide balanced design states on the failure modes of brace-to-gusset connection of SCBF systems:

$$R_{yield,mean} = R_y R_{yield} \le \beta_{y1} R_{y1} R_{yield,1} \le \beta_{y2} R_{y2} R_{yield,2} \le \ldots \le \beta_{yi} R_{yi} R_{yield,i} \quad (1)$$

$$R_{yield,mean} = R_y R_{yield} \le \beta_{y1} R_{y1} R_{yield,1} \le \beta_{fail,1} R_{fail,1} \le \beta_{fail,1} R_{fail,1} \le \ldots \le \beta_{fail,j} R_{fail,j} \quad (2)$$

in which $R_{yield,mean}$ designates the primary yield mechanism, and R_y represents the ratio of the expected yield stress to the minimum specified yield stress. Also, $R_{yield,i}$ and $R_{fail,i}$ denote the nominal resistance for the possible yield mechanisms and probable failure modes, and the balance factors β_{yi} and $\beta_{fail,i}$ are used to control their resistance, respectively. The above approach was basically focused on the gusset-brace subsystem for simply the tensile yielding of the braces, and accommodated only new elliptical clearance of the gusset plate connection.

Following the collapse assessment of DBMRFs in Lotfollahi *et al.* (2011), a new and improved balanced design criteria for DBMRF systems has thoroughly presented in Lotfollahi *et al.* (2015) through which the ductility values for the entire DBMRFs are substituted to the resistance, and the β factors are construed via the nonlinear displacement separations for the formation of yield mechanisms and failure modes in each level of nonlinear system performance. Hence, the previous states are substituted with the following expressions:

$$\Delta_y \le \Delta_{y1} \le \Delta_{y2} \le \ldots \le \Delta_{y(i-1)} \le \Delta_{yi} \equiv 1 \le \mu_{y1} \le \mu_{y2} \le \ldots \le \mu_{y(i-1)} \le \mu_{yi} \quad (3)$$

$$\Delta_y \le \Delta_{y1} \le \ldots \le \Delta_{yi} \le \Delta_{f1} \le \Delta_{f2} \le \ldots \le \Delta_{fj} \equiv 1 \le \mu_{y1} \le \ldots \le \mu_{yi} \le \mu_{f1} \le \mu_{f2} \le \ldots \le \mu_{fj} \quad (4)$$

where primary yield displacement (Δ_y) is followed by the displacements of multiple secondary yield mechanisms (Δ_{yi}) and probable failure modes (Δ_{fj}) of the system. The above states indicate an balanced dissipative hierarchy/sequence of secondary yield mechanisms and probable failure modes in which the values of calculated ductility for all the yield mechanisms (μ_{yi}) should be calibrated to be smaller than the ductility of probable failure modes (μ_{fj}). Furthermore, the undesirable failure modes should have adequate displacement separation (i.e., either greater μ_f values or lack of formation) than the occurrence of desirable failures. Thus, participation of all system constituents are considered in which both tensile yielding and compressive buckling of continuous/discontinuous X-bracing diagonals can be well prescribed. The proposed criteria are based on non-dimensional formulation and it can be implemented on various types/sizes of corner plates and different mid-connection details very efficiently. Thus, it can be extended to a wide range of the X-BMRF systems.

This latter approach provides a set of newer, more robust and improved criteria for multiple secondary yield mechanisms of X-BMRF systems compared with the primary approach that follows only the common design method hereof. Hence, in order to monitor widespread nonlinear performance of subsystems, *viz.*, moment resisting frame (MRF) and gusset-brace (gs-br), the following controls are supplemented to Eqs. 3 and 4 (i.e., currently known as balanced design or *bal.*) and the results are compared with those obtained from the earlier balanced failure occurrences in Eqs. 1 and 2 (i.e., currently called as conventional design or *conv.*):

$$(\varphi_{lin.}^{gs-br})_{bal.} \ge (\varphi_{lin.}^{gs-br})_{conv.}\ ;\ (EDR_{nonlin.}^{X-BMRF})_{bal.} \ge (EDR_{nonlin.}^{X-BMRF})_{conv.} \quad (5)$$

$$(\varphi_{PL_x}^{gs-br})_{bal.} \geq (\varphi_{PL_x}^{gs-br})_{conv.};\ (EDR_{PL_x}^{gs-br})_{bal.} \geq (EDR_{PL_x}^{gs-br})_{conv.} \quad (6)$$

$$(\varphi_{PL_x}^{gs-br})_{bal.} \geq (\varphi_{PL_x}^{MRF})_{bal.};\ (EDR_{PL_x}^{gs-br})_{bal.} \geq (EDR_{PL_x}^{MRF})_{bal.} \quad (7)$$

in which *EDR* and φ represent energy dissipation ratio of and load share of story shear between the subsystems, when the *lin.* and *nonlin.* subscripts denote to states of linear and nonlinear post-buckling responses of the subsystems, respectively. The nonlinear state in this study accommodates rigorous performance levels (PL_x) including all the secondary yield mechanisms (y_i), probable failure modes (f_i), and ultimate state of the system (*max*), as explained by Eqs. 3 and 4, and will be deliberated later on within this study. The undesirable failure modes are suppressed here using either the AISC design approach (AISC 2010a) or the privilege of previous balanced failure events (Eqs. 1 and 2) and their associated experiments (Roeder *et al.* 2011b).

NUMERICAL MODELING

In this study, the finite element software package, ABAQUS/Standard and /Explicit are utilized to perform monotonic, and cyclic analyses of the X-BMRF systems. The gusset-brace, and moment frame subsystems, and the connection details are modeled by a four node doubly curved general purpose element with reduced integration and hourglass control (S4R). The geometric nonlinearity phenomenon is also included as a result of large displacements with small strains. The gusset plates are merged to the beams and columns in order to replicate gusset plate connection with enough fillet welds as it is specified by the previous balanced design approach (Lehman *et al.* 2008). The top flanges of top beams are restraint against out-of-plane displacement to mimic the effects of floor slab. The gravity loads are assumed to transmit by transverse beams to beam-column connections, and the lateral loads are applied to the top flange of the top beams to resemble the rigid diaphragm.

Two complementary techniques for predicting the buckling mode shapes and post buckling response in each direction of lateral loading are implemented. First, an Eigen-buckling analysis to calculate eigenvalues, each associated with a buckled mode shape as an idealized elastic response. Next, the above mode shapes are properly scaled with either a small destabilizing load or an initial imperfection to generate the preliminary X-bracing geometry, and to initiate the solution of a desired post buckling response. The subsequent inelastic FE analysis needs these initial configurations to numerically converge and provides more accurate post-buckling response in order to consider the effect of material, and geometric nonlinearities through the X-BMRF systems.

FINITE ELEMENT MODEL VALIDATION AND VERIFICATION

The experimental data by Roeder *et al.* (2011a), and the companion numerical simulations by Yoo *et al.* (2009) were utilized to validate/verify the accuracy of the proposed three-dimensional finite element modeling (3D FEM) approach, as well as the boundary conditions, mesh sizes, and loading procedures. The test specimen from that experiment was modeled and analyzed in the current study and the obtained results are compared with the outcomes from original test for the "TCBF1-1" specimen, and the previously FE modeling simulations labeled as "2MFEP". The complete frame dimension/geometry, member properties of the test model and the details/dimensions of gusset-brace system of the related test model involved in the present study are provided in Table 1. The material properties adopted from their original published data are given in Yoo *et al.* (2009).

Figure 1(a) depicts the corresponding Mises stress distribution at the ultimate state of TCBF1-1 model. As shown, significant plastic deformations are taken place in the X-bracing diagonals, corner and mid span gusset plates; however, the frame members experience moderate inelastic stress level. The same consequences in each level of lateral loading are reported by the previous test (Roeder *et al.* 2011a) and simulation (Yoo *et al.* 2009).

Figure 1(b) shows the results obtained from the current FE simulations compared with the envelopes of the cyclic lateral force-drift curve of TCBF1-1 specimen (global response) obtained from the experimental data by Roeder *et al.* (2011a). As indicated, the agreement between present 3D-FEM and earlier experiment data is very well with maximum differences being 5.2% and 3.7% in tension and compression regions, respectively.

The equivalent plastic strain, as later described in this paper, is a scalar index operated as a quantitative measure to identify the failure modes (local response) in the localized regions with intensive plastic deformation and high stress/strain concentration. Figure 1(c) presents the typical calculated values of this parameter versus the lateral

displacement ranges of 2MFEP model in the middle of X-bracing diagonals and reentrant corner of mid span gusset plates obtained from the cyclic analysis of the system (omitted here for brevity). The results show a very good conformity between the current simulated equivalent plastic strain with the similar outcomes from the previous numerical simulations wherein the failure modes due to the fracture are also included (Yoo *et al.* 2009).

The results presented herein for numerical modeling and validation/verification procedure are summarized for sake of brevity. The outcomes finally indicate that it is possible to assuredly extend the previously described 3D FEM and analysis techniques to X-BMRF geometries/specifications beyond those validated here; and thus, the expected response of various X-BMRFs can be worthily calculated within the proposed balanced design criteria.

X-BMRF MODEL MATRIX

In this section, with the aim of developing numerical simulations that can revive the experiments, multitudes of single story, single bay X-BMRFs with common width-to-height ratio (B/H = 1.5, where H = 3.5 m) are designed according to the AISC 341-10 (2010b) provisions and AISC 360-10 (2010c) rules (see, Figure 2a, b). The load and load combinations are obtained from ASCE 7 (2010) to resist lateral load in a highly seismic area using a stiff soil site in Los Angeles, California. The X-BMRF systems should comply with the requirements of lateral-seismic-force-resisting systems, and their X-bracing subsystems comprise of hollow square section (HSS) diagonals with various section properties, and different types/sizes of corner and mid connection gusset plates.

The gusset-brace systems are designed according to the "special concentrically braced frames requirements" wherein the axial capacities of the corner/middle gusset plate connections are exactly set equal to the expected axial capacities of the X-bracing diagonals. Moreover, the limit states for design of gusset plates (*viz.*, yielding and fracture on the Whitmore width, block shear rupture, gusset plate buckling and interface weld failure) are prescribed here based on the preliminary balanced design approach (Roeder *et al.* 2011b) presented by Eqs. (1) and (2). The required interface weld of gusset plates to the frame members are calculated according to the expected tensile strength of corner plates. The net section failure are prevented and the welded brace-to-gusset connection length are also checked to avoid the failure by the base metal and the weld (filler metal).

The frame members are designed according to the "special moment frame requirements" by the following capacity-design principals. The beams and columns are also checked to resist additional demand based on the expected strengths from the X-bracing diagonals. The "weak beam-strong column" design rule is employed to ensure the formation of full plasticity across the gusset-brace system, and in turn the frame members can resist the corresponding forces from the X-bracing system. Accordingly, plastic hinges are only allowed to from at the beams ends, and at the lower ends of columns; however, the whole system would remain stable even after the ultimate state of the system. The beam-to-column connections at beam ends are designed according to the Welded Unreinforced Flange-Welded Web (WUF-WW) prequalified connection. All code limitations and related provisions are included over the design of these connections, and the connection components are carefully modeled through the proposed 3D FEM. The panel zone thicknesses and beam-to-column connection details are designed based on the current codes and provisions with the capacity exactly equal to the demand.

The frames of all X-BMRFs considered here are identical, and have W10×26 and W12×50 sections for the

beams and columns, respectively; but they have different rectangular and tapered corner and mid connection gusset plates. The middle gusset plate connections are designed here based on the common through-plate connection detail to accommodate different likely brace end rotations at the discontinuous diagonals during the execution of the proposed balanced design criteria, since the sandwich plate detail provides almost complete continuity across the center splice connection of diagonals intersection. In order to consider various brace-to-frame rigidity ratios, X-bracing systems are designed according to different demand-to-capacity (*D/C*) ratios (*viz.*, 0.45 ~ 1.25), and the axial capacity of corner and middle gusset plate connections is set exactly equal to the expected axial capacity of X-bracing diagonals. Each model is tagged by the gusset plate shape of either rectangular (*R*) or tapered (*T*), width-to-height (*B/H*) ratio of the frame, gusset plate thickness (in mm), and value of the demand-to-capacity ratio of gusset-brace system as presented in Table 3 for typical X-BMRFs (e.g., *D/C* = 0.45 and 0.85 for rectangular gusset plates, and *D/C* = 0.85 and 1.25 for corner gusset plates).

MATERIAL PROPERTIES

The material properties of the braces, gusset plates, and frame members are adopted from the ASTM A 500, ASTM A 572, and ASTM A 992 conventional structural steel standard, respectively (see for example Yoo et al. 2009). The uniaxial stress-strain diagrams for these three types of steel (all with E = 205 GPa and ν=0.3) are shown in Figure 2c. The stress-strain diagrams of all three cases are piecewise-linear, and data points of the stress-strain diagrams were obtained here in this study from a best fit of the Ramberg-Osgood formula (1941). Thus, the transition region from elastic to plastic behavior is kept highly refined, which improve numerical convergence in the nonlinear FE simulations. The yield stress values for the brace, gusset plates, and frame members are 345 MPa, 415 MPa, and 420 MPa, respectively; and isotropic hardening is adopted for all materials. Finally, a b ilinear behavior is extracted from the above multilinear behavior and the results are implemented into a kinematic material behavior in order to be utilized for the cyclic analysis.

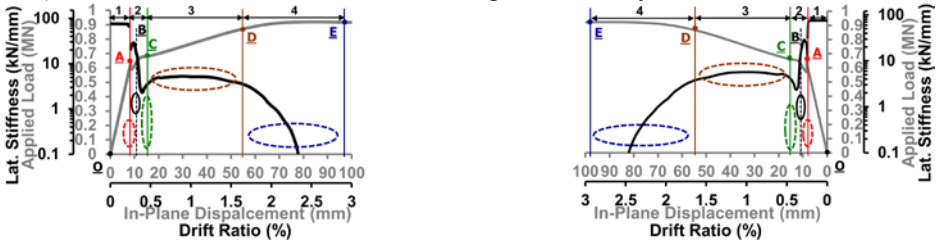
GENERAL BEHAVIOR OF X-BMRF

In order to performance-based seismic evaluation leading to balanced design criteria of X-BMRFs, the nonlinear post buckling response of such systems should be systematically characterized. Thus, two types of graphs, viz., the graphs in Figure 3 (a, b) for the "lateral load-displacement", and "lateral stiffness-drift ratio" are employed herein. Also, cyclic analyses of each X-BMRF with the increasing-amplitude drift cycles according to the ATC protocol (ATC 1992) are employed herein to calculate the nonlinear responses and to ascertain the performance levels indicated by different regimes of Figure 3. Next, the values of ductility for the formation/occurrence of multiple secondary yield mechanisms and probable failure modes of each X-BMRF system shall be calculated.

Monotonic (Pushover) Analysis

The general behavior of X-BMRFs in each direction of lateral loading (or through the push of subsequent cycles of loading, unloading, and reloading) can be outlined by dividing the abovementioned response curves into the four regimes. Attributes of behavior in each regime are described below:

Part OA: At relatively low lateral load, the initial stiffness of the X-bracing system is almost rapidly activated. The moment frame is nearly ineffective, and the X-bracing slender diagonals endure equal tensile/compressive elastic strains result in almost symmetric elastic diagonal axial forces. By increasing the load, a small out of plane bending deformation occurs in compressive diagonal as a result of imposed initial imperfection. At the same time, the tensile diagonal undergoes nearly elastic response (dependent on the ratio of *D/C*), and the stress levels in the frame members are very low. Subsequently, the stress in compressive diagonal exceeds the critical stress, and it entices the X-bracing diagonals to be onset of buckling. The X-bracing system undergoes out-of-plane deformation which can persuade inelastic post-buckling response and sudden loss of stiffness through the next step (point A). The frame members are elastic and the gusset-brace system is on threshold of nonlinearity.



(a) First mode of buckling deformation (b) Second mode of buckling deformation

Figure 3 Typical curves of X-BMRF (a) Lateral load vs. Displacement and (b) Lateral stiffness vs. Drift ratio

Part AC: The system undergoes geometric nonlinearity due to the X-bracing buckling which induces temporarily instability in the system, and yields in significant loss of the lateral stiffness. The compressive diagonal experiences out-of-plane deformation due to the pre-calculated mode shapes imposed as initial imperfections. Subsequently, the tensile diagonal becomes rapidly more effective, and the truss action of X-bracing system causes the post buckling response to be practically in snap-back behavior (rather than snap-through of similar system with diagonal bracing). Thus, the moment frame action becomes more effective, and this ensues previous instability to be restored almost immediately after compressive diagonal buckling. Meanwhile, the out-of-plane deformation of buckled diagonals is on the increases, and in turn plastic hinges form at the middle of compressive diagonals (point B). The X-bracing system experiences plastic deformation and its resistance deteriorates, but tensile brace action can soon survive stiffness being adequately proliferated. By increasing the load, tensile diagonal yields and the system undergoes considerable loss of lateral stiffness due to the nearly complete yielding of X-bracing diagonals (point C). The compressive diagonal is in the post buckling stage, and the tensile diagonal became fully plastic, whilst the frame members remain nearly elastic.

***Part CD*:** The X-bracing is almost ineffective and its response is subjugated to kinematic and material nonlinearities which imply on large post buckling deformation. Lateral stiffness is constantly being continued for a considerable lateral displacement range, but considerably less than the initial elastic stiffness. The yield points spread out through the corner gusset plates that is somehow yielding stage prolonged from the previous stage—i.e., dependent on corner gusset plate types/sizes and mid-connection details. Further increase of lateral load results in plastic hinge formation in both ends of compressive diagonal throughout the corner gusset plates. The system experiences a significant loss of stiffness, and finally the gusset-brace system becomes almost completely ineffective due to the significant plasticity distribution in the X-bracing system. Subsequently, more stiffness degradation occurs, mainly due to the first yielding occurrences in the frame members, which can be led to yielding of panel zone, and partial/complete plastic hinge formation in the beam members (point D). Not surprisingly, the gusset plates of tensile diagonal remain elastic even after brace element complete yielding. A partial mechanism develops across the gusset-brace system—i.e., triple plastic hinge formation in compressive diagonal and complete yielding of tensile diagonal—and plastic hinges spread out within the beams.

***Part DE*:** Through the last regime, the X-BMRF response becomes highly inelastic, and substantial input energy are dissipated. The gusset-brace system is completely lost its effectiveness due to the fully yielded diagonals and widespread plasticity of gusset plates in previous step, and partial and complete plastic hinges spread in the frame members as well. By increasing the load, the stiffness becomes decreased gradually even after the plasticity being fully spread out in the beams, and it finally remains nearly constant at a very low level. Consequently, the system experiences constantly maximum capacity with almost zero stiffness for a considerable range of lateral displacement, whilst the plasticity propagate partially at the columns. The system reaches to the ultimate state by forming the plastic hinges at the bottom of support, and along the length of

columns in the vicinity of gusset plates to the columns (point E). Figure 4(a) shows the typical Mises stress distribution corresponding to point E, in which as seen at the ultimate state, the X-bracing system becomes entirely inefficient, and excessive plasticity broadcasts throughout the moment frame.

Figure 4 Typical results of (a) Von mises stress in X-BMRFs at the ultimate state, (b) X-BMRF cyclic analysis

Cyclic Analysis

The failure modes of the X-BMRF system (i.e., tearing of welds and/or fracturing of members) can be estimated by computing the equivalent plastic strain (ε_{eqv}^{pl}) and by comparing its value to those visibly observed in the experiments. An accurate application of this parameter to indicate the occurrence of failure modes in the DBMRF systems have been recently presented in Lotfollahi *et al.* 2015. The adopted criteria therein acknowledged calculation of ε_{eqv}^{pl} and establishing threshold values by using the visual observation in the companion experiments (see Yoo *et al.* 2009) . In this paper, we consider the same strategy to perform cyclic analyses (see for example Figure 4b) and to indicate the failure modes within the X-BMRF systems. To wit,

- ε_{eqv}^{pl} in range of 0.054-0.065 represents weld cracking of *corner* gusset plates at re-entrant corner of column,
- ε_{eqv}^{pl} in range of 0.033-0.055 represents weld cracking of *corner* gusset plates at re-entrant corner of beam,
- ε_{eqv}^{pl} in range of 0.271-0.306 represents brace fracturing in centre of locally buckled X-bracing *diagonals*.

The aforementioned equivalent plastic strain above is computed using the general von Mises equation, as in

$$\varepsilon_{eqv}^{pl} = \frac{1}{\sqrt{2}(1+\tilde{\upsilon})}\left[(\varepsilon_x^{pl}-\varepsilon_y^{pl})^2+(\varepsilon_y^{pl}-\varepsilon_z^{pl})^2+(\varepsilon_z^{pl}-\varepsilon_x^{pl})^2+\frac{2}{3}(\gamma_{xy}^{pl\,2}+\gamma_{yz}^{pl\,2}+\gamma_{zx}^{pl\,2})\right]^{1/2} \quad (8)$$

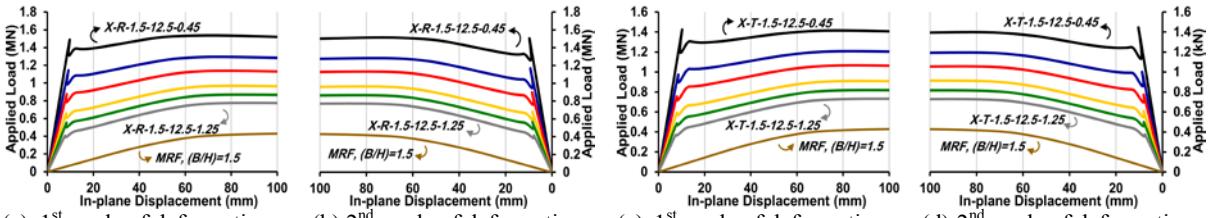
in which ε_x^{pl} , ε_y^{pl} , γ_{xy}^{pl} , etc., are the plastic strain components, and $\tilde{\upsilon}$ denotes an "effective Poisson's ratio of 0.3". The equivalent plastic strain depends on the FE mesh refinement; and thus, element sizes should be kept constant among the FE models of the X-BMRF model matrix in critical locations; and those sizes were selected based on a comprehensive mesh-sensitivity study (details of those investigations are omitted here for brevity).

NONLINEAR BEHAVIOR AND STIFFNESS VARIATION

The lateral load *vs.* displacement curves of the X-BMRF model matrix are displayed in Figure 5. The results show that the X-BMRF systems with a lower ratio of *D*/*C* (i.e., higher rigidity ratio of the gusset-brace to the moment frame subsystems) experience higher buckling load, and also the system experiences more elastic loading before the compressive buckling of X-bracing systems when either continuous or discontinuous diagonals buckle; however, they have a greater unstable displacement region due to the softening behavior of the system. Furthermore, the results show that different lateral loading directions (i.e., corresponding to either compressive buckling or tensile yielding of continuous and discontinuous diagonal) provide different buckling load and post buckling strength in the X-BMRFs. Moreover in the final stage, the ultimate load of X-BMRFs in both rectangular and tapered gusset plate connections increases linearly with the decrease of the ratio of *D/C*.

The primary yield mechanism displacements (Δ_y), and loads (P_y) of X-BMRFs in each direction of lateral loading are related to the initial buckling of the X-bracing system in which either continuous or discontinuous diagonals undergoes compressive buckling. The ultimate state loads (P_{max}) and displacements (Δ_{max}) of the X-BMRFs are defined as the state at which full plastic hinges form within the system, and is generally equal to the displacement reached when the system's lateral stiffness becomes zero. In most cases, this state is beyond the well-known 2.5% drift ratio of such systems recommended by the current design code (ASCE 7 2010).

Figure 6 shows the lateral stiffness *vs.* drift ratio curves of the X-BMRF model matrix. The results show that the initial lateral stiffness of the X-BMRFs are lost after buckling of the X-bracing diagonals either continuous or discontinuous. Remarkably, the lower ratio of *D/C*, the greater negative lateral stiffness of the X-BMRF after X-bracing buckling; and thus, the system experiences a more sizable instability region. After the formation of plastic hinges in the middle of either continuous diagonals at drift ratio of 0.27% in the first mode of buckling deformation (1st mode) or discontinuous diagonals at drift ratio of 0.25% in the second mode of buckling



(a) 1st mode of deformation (b) 2nd mode of deformation (c) 1st mode of deformation (d) 2nd mode of deformation

Figure 5 Lateral load *vs.* Displacement curves for (a, b) rectangular, and (c, d) tapered gusset plate connections

deformation (2nd mode), the gusset-brace system becomes less effective and all curves tend to converge toward each other and merge to the state of an open frame system. After the drift ratio of 0.39% in the 1st mode (when the tensile discontinuous diagonal yields) or after the drift ratio of 0.37% in the 2nd mode (when the tensile continuous diagonal yields), the X-bracing system becomes almost ineffective. Finally, after the drift ratio of 0.54% in the 1st mode or after the drift ratio of 0.43% in the 2nd mode (when the gusset plate in both ends of continuous/discontinuous diagonals becomes fully plastic, and discontinuous/continuous diagonals completely yields), the truss action of X-BMRFs is nearly completely lost, and the remaining shear story is resisted by the frame action. More increasing of lateral deformation results in the fully plastic hinges formation at the beam-ends at a drift ratio of 1.35%, but due to the "weak beam-strong column" design criteria, the columns undergo partial plastic hinge formation. Thus, there is an adequate displacement range available to the X-BMRF system to develop widespread plastic hinge formation through the system till the ultimate state.

DUCTILITY EVALUATION AND COLLAPSE ASSESSEMNT

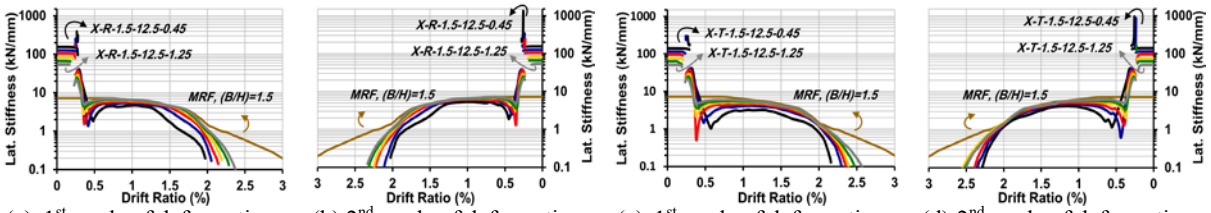
The ductility values corresponding to the *i-th* yield mechanisms, *j-th* failure modes and ultimate state of the X-BMRF model matrix are separately calculated in each direction of lateral loading as in $\mu_{yi} = \Delta_{yi}/\Delta_y$, $\mu_{fj} = \Delta_{fj}/\Delta_y$, and $\mu_{max} = \Delta_{max}/\Delta_y$. The yield point ($P_y$, Δ_y) of the X-BMRF system are obtained by recording the out-of-plane displacement of the buckled continuous/discontinuous diagonals, and by extracting the bifurcation point of the gusset-brace system in each direction of lateral loading. The target displacements corresponding to different performance levels of each X-BMRF system in the 1st and 2nd modes of buckling deformation are defined as follows: Δ_{y1} = plastic hinge formation in the middle of buckled segment of (continuous/discontinuous) X-bracing diagonals; Δ_{y2} = tensile yielding of the (discontinuous/continuous) X-bracing diagonals; Δ_{y3} = plastic hinge formation in both ends of buckled (continuous/discontinuous) X-bracing diagonals across each corner gusset plate; Δ_{y4} = first yielding of the beam elements; Δ_{y5} = complete yielding of the panel zone; Δ_{y6} = full plasticity of the beam element; Δ_{f1} = failure modes occurrence in the system corresponding to the brace fracturing and/or gusset plate weld tearing; Δ_{max} = ultimate state of the system. Figure 7 display the values of ductility for the secondary yield mechanisms, probable failure modes, and ultimate state of the proposed X-BMRF model matrix. The results along with the energy dissipation ratios and contribution shares of story shear through the presented X-BMRF model matrix are summarized in the following subsections.

First mode of buckling deformation

In the case of rectangular gusset plate connection with $D/C \geq 0.85$, a desirable sequence of secondary yield mechanisms are attainable; and thus, the system meet the requirement of a balanced design. For $D/C = 0.75$, first yielding of the frame members and plasticity of the gusset plates occur concurrently. For $D/C \leq 0.60$, gusset plates plasticity is recorded after first yielding of the beams, and this, along with complete plastic hinge formation of the beams prior to full yielding of the panel zones, results in lower X-BMRF ductility (a thinner gusset plate here in which the undesirable failure modes are prevented would yield on a X-BMRF system with higher ductility). Instead, in the case of tapered gusset plate connection, for $D/C \geq 0.75$, a desirable sequence of secondary yielding mechanisms is obtained; and the X-BMRF acts as an almost balanced system. For $D/C = 0.60$, tensile yielding of the X-bracing diagonals and first yielding of the frame members occur almost simultaneously, while plasticity of the gusset plates occurs prior to yielding of the tensile diagonal. For $D/C \leq$

0.45, complete yielding of the tensile diagonal and plasticity of the gusset plates are happened after first yielding of the frame members. As such, a thicker gusset plate is required to attain higher X-BMRF system ductility.

As example, the use of D/C = 0.85 instead of 0.95 for the rectangular gusset plate connection in the 1st mode of buckling deformation results in increasing of *EDR* by 12.1%, 7.8%, 5.3%, and 3.3% for the performance levels of *B*, *C* , *D*, and *E*. Furthermore, from D/C = 0.95 to 0.85 at the ultimate state of the system (*E*), the increase of 12.3% in the *EDR* of gusset-brace system corresponds to the decrease of 7.4% in the *EDR* of moment frame system (see Figure 8) . Moreover, using D/C = 0.85 instead of 0.95 results in the increase of 27.8% for the φ of



(a) 1st mode of deformation (b) 2nd mode of deformation (c) 1st mode of deformation (d) 2nd mode of deformation

Figure 7 Calculated ductilities of secondary yield mechanisms (Y.Ms.) and probable failure modes (F.Ms.)

gusset-brace system that is corresponded with the constant φ in moment frame system (see Figure 9).

Second Mode of Buckling Deformation

In the case of rectangular gusset plate with $D/C \geq 0.95$, plasticity of the gusset plates and tensile yielding of the X-bracing diagonals occur almost at the same time. For $D/C \leq 0.85$, gusset plate plasticity occurs after tensile yielding of the X-bracing diagonals. Moreover, the results show that (i) for $D/C \geq 0.75$, first yielding and partial plastic hinge formation in the beams occur after the gusset plate plasticity, (ii) for D/C = 0.60, gusset plate plasticity and first yielding of the frame members are happened simultaneously, and (iii) for $D/C \leq$ 0.4, plasticity of the gusset plates occur after first yielding (or partial plasticity) in the frame members. Thus, for $0.75 \leq D/C \leq 0.85$, a balanced sequence of secondary yield mechanisms and optimum plasticity propagation through the system are achievable; and thus, the system exhibit the benefit of a balanced design. Instead, in the case of tapered gusset plate connection with D/C = 1.25, tensile yielding of the X-bracing diagonals and plasticity of the gusset plates occur simultaneously. Additionally, for $0.75 \leq D/C \leq 0.95$, tensile yielding of the X-bracing diagonals occur after plasticity of the gusset plates; and for $D/C \leq 0.60$, plasticity of the gusset plate occur after tensile yielding of the X-bracing diagonals. Likewise, the results show that (i) for $D/C \geq 0.85$, first yielding of the frame members occur after plasticity of the corner gusset plates, (ii) for $0.60 \leq D/C \leq 0.75$, the aforementioned yield mechanisms are happened almost concurrently and the system acts as an almost balanced system, and (iii) for $D/C \leq 0.45$, plasticity of the corner gusset plates occur after first yielding of the frame members. Thus, for $0.60 \leq D/C \leq 0.75$, a desirable balanced dissipative behavior of the inelastic post buckling behavior are acquirable; and thus, the system meets the requirement of a balanced system.

As example, the use of D/C = 0.75 instead of 0.95 for the tapered gusset plate connections in the 2nd mode of buckling deformation results in increasing of *EDR* by 20.1%, 14.9%, 10.1% and 7.8% in the performance levels of *B*, *C*, *D*, and *E*. Furthermore, from D/C = 0.95 to 0.75 at the ultimate state of the system (*E*), the increase of 24.3% in the *EDR* of gusset-brace system corresponds to the decrease of 16.8% in the EDR of moment frame system (see Figure 8). Moreover, using D/C = 0.75 instead of 0.95 results in the increase of 64.2% for the φ of gusset-brace system that is corresponded with the constant φ in the moment frame system (see Figure 9).

CONCLUSIONS

If X-BMRFs are designed according to the current provisions and rules, they may provide adequate ductility, but do not necessary exhibit optimum hierarchy/sequence between the secondary yield mechanisms and desirable failure modes. To wit, the moment frame system may have premature plasticity, the gusset-brace system may experience incomplete yielding hierarchy, and undesirable failure modes may interfere into the formation of yield mechanisms. This is in contradiction with capacity design principles stated in the current seismic design codes/provisions. Besides, the multiple secondary yielding hierarchy (during the minor and moderate earthquake motions) are superior than the probable failure modes for attaining a maximum system ductility and to improve balanced dissipative behaviour, while all the previous approaches are dealt with the failure modes of gusset-to-brace connections. The proposed methodology in this study represents a set of newly

improved balanced design criteria for the X-BMRF systems that can substantially rectify all the above shortcomings. The method is based on non-dimensional formulation, using the influential/robust design parameters and examined responses, and consider local and global behaviours of all system constituents. However, the effect of different frame geometries and specifications and various corner gusset plate connections and mid connection details are not presented here; and thus, the results are limited to the frames with B/H =1.5, having linear clearance rectangular/tapered gusset plates connections, and through plate mid connection detail.

FRAGILITY AND SAFETY MARGIN ANALYSIS OF RC FRAMES HAVING EUQAL CONSTRUCTION COST

Zheng WANG, Zheng HE *, Yongan SHI

*E-mail: hezheng1971@126.com (Z. He)

ABSTRACT

An effort is made to compare seismic fragility and collapse resistance of three 12-story reinforced concrete (RC) frames with a premise of equal construction cost. These frames, i.e. basic frame, frame with buckling restrained braces (BRBs) (called BRB frame) and frame with lead-rubber isolating bearings (LRB) (called isolated frame), are modeled with OpenSees. According to ATC-63, seismic fragility analyses are conducted with incremental dynamic analysis (IDA) method to compute collapse margin ratios (CMR). Three performance levels prescribed by FEMA356 are grounded on. This paper also considers the influence of possible price fluctuation of passive controls on the analytical outcome. The case study indicates that with a premise of the same construction cost, base isolation frame possesses better seismic performance and higher safety reserve than BRB frame and basic frame at all three performance levels. Besides, frame with relatively larger number of BRBs can presents a better collapse resistance even than base isolation frame, while its performance improvement and safety reserve improvement at level Immediate Occupancy (IO) and Life Safety (LS) are much smaller than that of base isolation frame.

INTRODUCTION

Controlled RC frame adopts controls on conventional basic frame to improve its seismic performance. Comparing to basic frame, controlled RC frame achieves functional resilience more easily (Lu et al. 2011), where the retention of architectural function implies the reduction of direct and indirect economic losses. However, though effective, controlled RC frame hasn't extensively used as installation of controls would lift up construction cost. Besides, Since ATC committee (2010) developed research on collapse margin ratio, many scholars have utilized CMR to assess anti-collapse capacity of frame, e.g. research on the influence of column's axial compression ratio on anti-collapse capacity of Chinese RC frame (Tang et al. 2010), study on anti-collapse capacity of RC frames with different seismic fortification (Shi et al. 2011) and comparison of seismic fragility curves and CMRs between 3-story frames and 7-story frames (He 2012). Thus in this paper, for the 12-story RC frame in study, an attempt is made to find out an optimum structural type which possesses strongest seismic capacity and highest safety reserve with the cost remained steady. The optimum frame would increase safety reserve of single structure, improve resilience of local structure group and reduce post-seismic economic losses. Two typical passive controls, buckling restrained brace and lead-rubber isolated bearing, are used to strengthen the basic frame with the same cost.

Buckling restrained brace (BRB) acts both braces and passive energy-dissipation devices. Unlike traditional types of braces, BRB has a full and symmetric hysteric curve (Clark et al. 1999) and thus improve bearing capacity and plastic deformability of overall structure. Secondly, when encountering earthquake, BRB would yield to dissipate massive seismic energy to decrease the damage of main structure, acting as a seismic fuse. Thirdly, structural lateral stiffness is increased by BRB and structure's horizontal displacement is controlled.

Lead-rubber isolated bearing is an effective energy-dissipating device with relative high vertical bearing capacity and horizontal deformability. The insert of lead core provides horizontal restoring force, resulting in a large area of hysteric curve which means its excellent energy-dissipating capacity (Dang et al. 2007). Compared to the frame with fixed foundation, the adoption of LRB would endow the structure a longer fundamental period,

which would cause smaller acceleration and seismic action in accordance with elastic design spectrum. LRB can lessen the floor acceleration, velocity and story drift of upper structure and retains architectural function. On the other hand, plastic deformation would concentrate on LRB, convenient for failure mode control and indispensable replacement.

3-D models are established with OpenSees. Referring to ATC-63 (2010), 22 ground motion records are selected based on Chinese design spectrum, for computing structural response by IDA method. Taking Housner's spectral intensity as intensity measure (IM) and maximum story drift as damage measure (DM), with the three performance levels proposed by FEMA 356 (2000), drawn and compared are the seismic fragility curves of three frame types of concern.

DESIGN OF THREE FRAMES

Basic Design Data

As 12-story buildings with their standard floor of 598.5 m^2, the established frames are located in site class II and seismic group I. Seismic fortification intensity 8(0.2g) and seismic fortification class B are supposed. Structural damping ratio takes 5%. The followings present loads acting on the structure: roof permanent load 7kN/m^2, roof live load 0.7kN/m^2, floor permanent load 5kN/m^2, floor live load 2kN/m^2; linear load on exterior beams 6kN/m^2; and linear load on interior beam 3kN/m^2. Concrete grade C40 is used for beams, slabs and columns. Rebar takes HRB335. The slab has a thickness of 130mm.

Structural Dimensions

Figure 1 presents the architectural plan of basic frame. For BRB frame, to keep construction cost steady, alteration of the basic frame's columns is required to save money for purchasing and installing BRB. The cross-sections are reduced along structural height considering the magnitude of yield strength coefficients. Similarly, column sections of the basic frame have to be altered for addition of lead-rubber isolating bearing (LRB). In accordance with isolation design clauses in codes, the LRB is positioned under first floor in an additional isolation floor which has a height of 1.4m. All beams have a section of $b \times h$=300mm×600mm. Table 1 lists the dimension of all columns. Table 2 provides information about price and amount of steel and concrete used in basic frame and altered frame. The prices are given pursuant to Dalian Building Material Industry Quota Standard, China.

As for BRB frame, 113188RMB is saved by column alteration, which can afford 12 BRBs. The price is approximately 9000RMB for each BRB, consulting several BRB manufacturers. Specific parameters of the adopted BRB are shown in Table 3. Placement scheme (Figure 2) of the limited number of BRBs is determined after conducting an elastic-plastic time-history analysis with an artificial ground motion record to ascertain weak stories of the altered building (story 3, 6 and 9). The configuration of BRB takes chevron.

In term of base isolation frame, there are altogether 32 LRB600 bearings used while support reactions are primary criteria for choosing bearing type. Each bearing costs 10000RMB, installed using the saved money. Consultation from manufacturers is made to attain desirable information. Specific parameters are displayed in Table 4. The LRBs all locate under the columns of the isolation floor.

Design Check

In compliance with Chinese code (2010), two natural ground motion records and one artificial ground motion record should be selected for seismic check. The calculational results are exhibited in the Figure 3, 4, 5 and 6. It can be observed that story drift of basic frame and BRB frame is within the limit 1/550 prescribed for minor earthquake and does not exceed the limit 1/50 for major earthquake. As for base isolation frame, after calculation, compressive stress of LRB support is smaller than 12 MPa, complying with the limit proposed by code. And when subjected to rarely-occurred earthquake, LRBs experiences a tensile stress less than the code-specified limit1.0 MPa and a horizontal displacement below the maximum allowable value 330mm.

MODELLING AND SEISMIC FRAGILITY ANALYSIS

Modelling and Records Selection

Three frames are modelled by OpenSees, an open-source software frame work developed by Pacific Earthquake Engineering Research (PEER) centre (Mazzoni et al 2015). All the beams and columns are simulated by fiber beam-column elements. To reflect the confinement due to lateral reinforcement on concrete, an adjustment factor is applied in Concrete02 material. Confined core concrete and unconfined concrete cover are modelled, separately. Reinforcing bars are modelled by Steel02 material. Fiber beam-column elements have five integration points. The P-Delta effect is considered and rigid diaphragm is assumed. BRB can be simulated by Truss element (see Figure 7) (Zhang 2012) in which Steel02 materials is also adopted. The element ElastomericBearingBoucWen is used to simulate the behaviour of LRBs (see Figure 8).

It is critical to select appropriate ground motion records for incremental dynamic analysis. Referring to ATC-63 (2010), on the basis of design spectrum of Chinese code (2010), 22 ground motion records are chosen (see Table 5). The accelerative response spectrum and average response spectrum are shown in Figure 9, respectively.

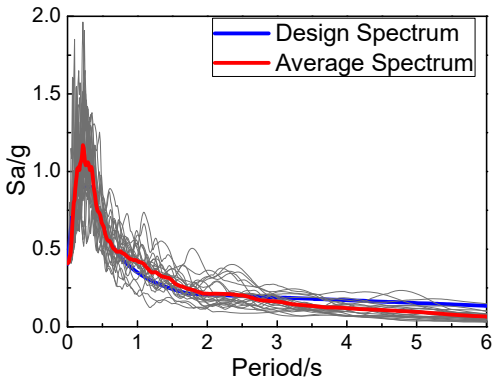

Figure 9 Acceleration response spectra

Incremental dynamic analysis (IDA) (Vamvatsikos and Cornell 2002) is a method for overall structural seismic capacity assessment. When conducting elastic-plastic time-history analyses on certain structure, IDA demands the scaling of each inputted ground motion record to different ground motion intensity, then based on structural responses, IDA curves, describing the relationships between damage measure (DM) and intensity measure (IM), are drawn. Structural seismic fragility are defined as the possibility of a damage degree for a structure, i.e. the possibility that a structure reaches certain performance level under different ground motion intensities.

The performance levels recommended in FEMA356 (2000), i.e. Immediate Occupancy (IO), Life Safety (LS) and Collapse Prevention (CP), are used for the RC frames in this paper. Table 6 exhibits the maximum story drifts of different performance levels of RC frames. As for base isolation frame, The structure would collapse when the LRB has its maximum displacement exceeding ultimate displacement or θ_{max}=4%

Table 6 Performance level

Structural performance levels	Inter-story drift ratio
Immediate Occupancy(IO)	1%
Life Safety(LS)	2%
Collapse Prevention(CP)	4%

The S_a (T_1,5%) recommended by ATC-63, which is related with structural fundamental period, is not an appropriate measure for seismic safety reserve assessment in the paper since the basic frame, BRB frame and

base isolation frame have different fundamental periods. Because for structures with distinct fundamental periods, PSV has close coefficients of correlation and presents relatively high correlation (Li 2014), Housner's spectral intensity (Housner 1952) is selected as ground motion intensity measure. The Housner's spectral intensity (SI) is defined as the area under pseudo-velocity response spectrum between 0.1s and 2.5s. Eq. 1 gives the corresponding expression, where ξ denotes structural damping ratio.

$$SI(\zeta) = \int_{0.1}^{2.5} S_v(T,\zeta)dT \tag{1}$$

The analytical outcomes are as follows. Each of the 22 ground motion records is inputted into one structure, with Housner's spectral intensity scaled, when maximum story drift θ_{max}=1%, performance level IO is reached, collection of calculation results of the 22 ground motion records could give seismic fragility curves, shown in Figure 10. Figure 11 exhibits the seismic fragility curves for level LS, i.e. θ_{max}=2%. When the maximum story drift reaches 4% or for base isolation structure, shear strain of LRB reaches 400%, it can be judged that the frame reaches CP level, whose corresponding seismic fragility curves are displayed in Figure 12. Figure 13 presents the seismic fragility curves of all performance levels.

It can be known from Figure 13, construction cost kept steady, safety reserve of base isolation frame are far greater than these of basic frame and BRB frame while BRB frame shares with basic frame almost the same seismic fragility curve, which indicates little improvement of safety reserve.

Design Plans Considering Price Fluctuation

In the consideration of price fluctuation of BRBs, four plans for BRB frame are given based on variation of BRB's parameters and quantity. Plan1: when in markdown sale, present price of an ever 9000RMB BRB is 4500RMB, then 24 BRBs are affordable, Figure 14 (a) shows corresponding placement scheme. Plan2: when in markdown sale, present price of an ever 13500RMB BRB is 9000RMB, then 12 BRBs with larger core plate cross-section (parameters presented in Table 7) are acquirable (see Figure 14 (b)). Plan3: with price in rise, present price of an ever 9000RMB BRB is 13500RMB, then only 8 BRBs can be afforded, corresponding placement scheme is as Figure 14 (c). Plan4: with price in rise, present price of an ever 4500RMB BRB is 9000RMB, then 12 BRBs with smaller core plate cross-section (parameters presented in Table 7) has to be used (see Figure 14(d)).

Besides, two plans for base isolation frame are taken into account in view of possible price fluctuation, where LRB of initial price 12000RMB and 8000RMB become 10000RMB at present. Table 8 exhibits bearing parameters for these two cases.

Table 7 Parameters of BRB

Ever price (RMB per set)	Present price (RMB per set)	Core material	Core shape	Core area(mm^2)	Section size(mm)	Yield force(kN)	Axis length(mm)	BRB length(mm)
13500	9000	Q235	Straight	15,000	400×400	3525	4920	3000
4500	9000	Q235	Straight	5,000	400×400	1175	4920	3000

Figure 14 Four plans of BRB frame

Table 8 Parameters of LRB

Ever price (RMB per set)	Present price (RMB per set)	Effective diameter (mm)	Lead diameter (mm)	Total rubber thickness (mm)	Initial stiffness (kN/m)	Post yield stiffness (kN/m)	Yield strength (kN)	Ultimate shear deformation
8000	10000	600	140	120	10519	842	130.78	γ=400%
12000	10000	600	140	200	6312	505	130.78	γ=400%

Parametric Fragility Analysis

There are four plans considered for BRB frame, if BRB price fluctuates, whose seismic fragility curves corresponding performance level IO, LS and CP are shown in Figures 15,16 and 17, respectively. From these figures, for all the four plans, BRB frame has a higher safety reserve than basic frame when approaching collapse. BRB plan1 can result in the highest anti-collapse capacity improvement, which may even higher than isolation frames. In that circumstance, the quantity and location of BRB can influence significantly structural anti-collapse capacity while BRB's cross-section area exhibits little influence. However, compared to basic frame at level IO and LS, the improvement of safety reserve of BRB frames is small, far smaller than that of isolation frame. As LRB's price changes as the plans for base isolation frame aforementioned, seismic fragility curves of base isolation frames at three performance levels are exhibited in Figures 18, 19 and 20, respectively.

It can be observed that at performance level IO and LS, when 8000RMB bearings are adopted, base isolation frame are still equipped with higher safety reserve than basic frame, while at CP performance level, these two frame structure share the same safety reserve. But when 12000RMB bearings are adopted, base isolation frame's safety reserve of three performance levels is far higher than that of basic frame.

COLLAPSE SAFETY MARGIN ASSESSMENT

Analysis on CMR

Grounded on seismic fragility analysis, collapse margin ratio (CMR) is defined by ATC-63 (2010) to reflect objectively structural anti-collapse safety reserve. As shown in Figure 21, CMR is defined as the ratio of the median IM, which results in collapse, to the MCE-level IM. Eq. 2 is the definition of CMR.

$$CMR = IM_C / IM_{MCE} \tag{2}$$

Figures 22, 23 and 24 exhibit structural collapse possibility curves. SI_{MCE}=134.860cm, computed according to Eq. 1. Scrutiny over the foregoing figures indicates that under rare earthquake, i.e. SI_{MCE}=134.860cm, all structures have a collapse possibility of 0, which means that these structures would not collapse under design earthquake. Table 9 presents CMRs of the three structures with same construction cost and Figure 25 shows the CMR results of the parametric plans.

From the above analytical results, when adopting BRB plan1 or LRB (12000RMB), structural collapse margin ratios are maximum, implying that anti-collapse capacity of corresponding plan is the strongest among the proposed plans. Further, structural collapse margin ratio also takes a relatively bigger value for BRB plan 3 and LRB (10000RMB). It is noteworthy that BRB plan 1 and BRB plan 3 both change quantity of BRB used; thus a conclusion turns up that it is the quantity of BRB used other than its cross-section area that possesses a

significant influence on structural anti-collapse capacity. Therefore, to improve structural anti-collapse capacity is to use more BRB on weak story or to adopt LRB with higher horizontal flexibility.

Structure	Basic frame	BRB frame	Isolated frame
$SI_{50\%}$ (cm)	517.993	528.962	610.939
CMR	3.841	3.922	4.530

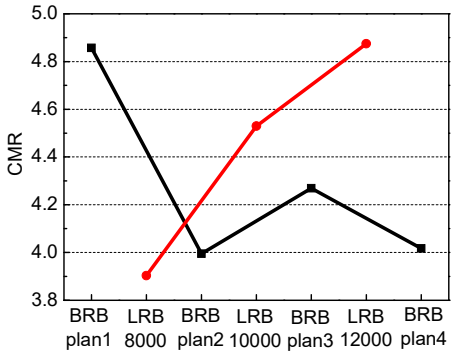

Figure 25 CMR results of several cases

CONCLUDING REMARKS

A fact is discovered in this study that without considering price fluctuation of controls, base isolation frame possesses better seismic performance and higher safety reserve than BRB frame and basic frame at all three performance levels with a premise of same cost. BRB frame exhibits a performance equivalent to basic frame and possesses safety reserve at all three performance levels similar to the basic frame.

Besides, allowing price fluctuation of BRB, when adopting BRB plan 1, frame with relatively large number of BRBs on weak stories could present an improved collapse resistance which is close to or even better than that of base isolation frame. But its seismic performance improvement and safety reserve improvement at performance level IO and LS are smaller than that of the base isolation frame. Thus it is the quantity of BRBs in appropriate position other than BRB's cross-section area that can influence the anti-collapse capacity of BRB frame significantly. To improve the anti-collapse capacity, with construction cost kept the same, employing more BRBs instead of choosing BRB with bigger cross-section should be preferred.

The safety reserve of base isolation frame varies as LRB's price fluctuates, but is still far higher than basic frame and BRB frame at performance level IO and LS. And when adopting LRB (12000RMB), structural safety reserve is the highest at performance levels IO and LS and structural anti-collapse capacity is the strongest. Therefore, in order to improve safety reserve at all three performance levels with the same cost, the adoption of LRBs with small horizontal stiffness and high yield strength is effective.
